THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, JULY 5, 1890. NO. 1.

ORIGINAL LECTURES.

REMARKS ON THE FREQUENCY AND CHARACTER OF THE PNEUMONIAS OF 1890.

An Address
delivered before the New York Academy of Medicine,
April 17, 1890.

BY WILLIAM PEPPER, M.D., LL.D.,
OF PHILADELPHIA.

IN attempting to give, in the few minutes at my disposal, a statement of the prevalence and peculiarities of pneumonia as it has presented itself in Philadelphia during the epidemic of influenza, I have tried to secure some reliable statistics by addressing nearly three thousand circulars to the physicians living in Philadelphia. To these I have had 272 replies, each more or less full. Dr. Benjamin Lee, the Secretary of the State Board of Health of Pennsylvania, has kindly given me the following returns, extending up to April 5th, as made to that Board, of the pandemic of influenza:

Total number of physicians giving returns		187
" " adults affected	19,868	
" " children "	8,258	
Total		28,126
Total number of nervous (as per returns)		5,275
" " catarrhal "		13,249
" " inflammatory "		4,976
" " deaths, directly caused	36	
" " " indirectly "	147	
Total		183
Immediate cause of death, bronchitis		4
" " pneumonia		86
" " phthisis		24
" " nervous symptoms		12

Through the kindness of my correspondents, to whom I desire to return my sincere thanks for their coöperation in this inquiry, I am able to submit statistics of 35,413 cases reported as above stated by 272 practitioners. From my personal knowledge of the profession in Philadelphia, I am disposed to believe that these figures do not represent a fair average, but that I have secured returns from an undue proportion of those who treated a considerable number of cases; I believe, however, that, so universally prevalent was the disease, not less than two out of every three, or, possibly, three out of every four of the eleven hundred thousand population of Philadelphia suffered from the disease in a greater or less severity. The figures which I have secured are probably sufficiently large to warrant some deductions as to the mortality of the disease, directly or indirectly, and as to the number of cases in which pneumonia appeared as a complication. The number of deaths in the 35,413 cases is given as 257, or 0.72 per cent. Of these 257, 84 are reported as directly due to influenza without pneumonia. Out of the total number of cases of influenza, pneumonia occurred in 1485, with a mortality of 173, or 11.65 per cent. There were also reported as occurring independently of influenza, 2471 cases of pneumonia, with a mortality of 324, or 13.11 per cent. Of these, 1046 are given as croupous, with a mortality of 151, or 14.43 per cent., and 1749 as catarrhal, with a mortality of 173, or 9.89 per cent.

It will be observed that of the 28,126 cases reported to the State Board of Health by 187 physicians in various parts of Pennsylvania, there were only 86 deaths from pneumonia. No mention is made of the total number of cases of pneumonia occurring, although it is probable that under the heading "Inflammatory cases," a considerable number of pneumonias were included. The individual experience of physicians has, however, varied greatly in this respect; thus, one of the most reliable of my respondents reports 1000 cases, with only three cases of pneumonia, each case of pneumonia terminating fatally. There were 10 other fatal cases, and it may be suspected that in some of these a concealed pneumonia was the cause of death, or at least was coexistent. Another respondent, of the highest distinction as a clinical observer, reported 850 cases of influenza with but 5 pneumonias and not a single death in the entire series. It is needless to say that the experience of those largely engaged in consulting practice is wholly without value from a statistical standpoint, and the same remark must be held applicable to the returns from hospitals.

A more complete notion of the great prevalence of pneumonia during the past season may be obtained from a chart, kindly prepared for me by Dr. Frederick A. Packard from the weekly returns of the Board of Health of Philadelphia. It is seen that during the period embraced between September 7th and December 28th there were, in 1888, 428 deaths from pneumonia, and during the same period of 1889 there were 453, or about an equal number of deaths from this disease; while during the period from December 28th to March 8th the deaths from pneumonia were, in 1889, 459; and, in 1890, 810. There was also a notable, but not equal, difference in the returns of deaths from bronchitis, and it cannot be doubted that the cases of death from pneumonia in 1890 would be further increased by the fact that some such cases are included under the head of bronchitis. In addition to this, the total number of deaths returned as from influenza, without specific mention of pneumonia, is 138, and unquestionably a large proportion of pneumonias are therein concealed. Finally, it will be noticed that during the five weeks from December 28th to February 1st, the number of deaths from pneumonia were, respectively, 71, 145, 182, 131, 82, a total of 611; while during the same weeks of the previous year the figures were, respectively, 44, 50, 38, 34, 55, a total of 221. The maximum number of deaths from pneumonia in one week in the winter 1888–9 was 64—in the week ending March 8th.

In attempting to estimate the relative proportion of the croupous and catarrhal varieties, the returns made to me (and which I must regard as more reliable than the aggregate returns to the city health office) would indicate that the catarrhal were almost twice as frequent as the croupous. It is no argument against this conclusion, as would be expected, when I say that Dr. Da Costa and myself saw at least as many cases of croupous as of catarrhal, in consultation, since this might be explained by the fact that the former were the more severe and dangerous (giving a mortality of 14.43 per cent. as against 9.89 per cent.).

In passing from this merely statistical return to the peculiarities of the pneumonias of the past season, I would first note the large preponderance of cases affecting the right lung. I should be inclined to say that this side was affected at least twice as often as the left. There was also an unusual proportion of cases of apex pneumonia where the entire upper lobe was completely consolidated without implication of any other part. As usual in such cases, there seemed to be a special predominance of cerebral symptoms.

It would appear that the association with pleurisy was even more constant and marked than usual. The side pain was often intense and sudden. The pleurisies were usually plastic; in one case, coming on with pneumonia immediately after exposure during convalescence, aspiration secured a pint and a half of pus on the third day and a few ounces of sero-pus from the pericardium on the following day.

I would offer merely as a suggestion resulting from personal observation that there has been an unusual prevalence of pericarditis, both plastic and purulent, in all probability, in some cases at least, associated with and preceding influenza. Corresponding prevalence of endocarditis has not been noted.

Jaundice has been observed in Philadelphia in a considerable proportion of cases, especially in those accompanied with pneumonia of the right lung. The evidence as to the cause of jaundice is not conclusive. In the cases where careful examinations were made bile pigment was detected. In the following case (Case I.), which may be quoted in full as typical, there were hæmin crystals found in the first examination of the urine, which was made prior to the development of the jaundice, and subsequently bile pigment was detected. In the only cases where autopsies were made the bile-ducts seemed pervious, although, as is well known, a preceding catarrhal swelling may have subsided just before or after death. Jaundice was certainly a symptom of highly unfavorable omen in pneumonic cases; when it occurred merely in the catarrhal form in influenza not complicated with pneumonia it was not necessarily grave.

CASE I.—N. C., aged twenty-five, unusually vigorous and athletic, was in excellent condition when attacked by a very slight form of influenza. He was not confined to bed at all and took no medicine and did not consult a physician. He stayed in the house but went to his meals, and in four or five days announced that he felt so well that he would go out after dinner to visit a friend a few blocks distant. The night was damp and raw. After sitting and conversing about an hour he was suddenly seized with a violent pain in the right side, which grew so intense that he fell upon the floor and vomited a quantity of blackish matter. It was not said, but it is not improbable that there was blood mixed with it. The vomiting was perhaps induced by brandy and ginger which was given to him. He was taken home in a carriage and I saw him within an hour from the time of the attack, and found him with temperature over 105° and with the evidences of the congestive stage of pneumonia of the right lower lobe. He had a hypodermic of morphine to allay pain, took aconite at short intervals during the night with antipyrine and salicylate of sodium, each 5 grains. During the night pain was intense, the respirations were short and gasping and the face wore an anxious expression. The hypodermic of morphine and atropine had to be repeated. The following morning the temperature had fallen to 103° and at no time subseqently did it reach 105° till just before the fatal ending. Complete consolidation of the right lower lobe developed at the end of forty-eight hours; the cough was painful with rusty sputa; until the fourth day the temperature averaged from 102° to 103° and the pulse between 90 and 100. The stomach was irritable and retained only very small quantities of liquid. The tongue was heavily coated; the bowels were quiet. The urine was scanty, dark, and contained albumin and granular casts. He was treated with large doses of quinine by suppositories, and repeated half-grain doses of calomel until 10 grains had been taken. At the close of this time, about the fifth day, there were several loose stools of light color. The patient seemed to be doing extremely well and frequently expressed himself as improving. By this time the rapid extension of disease began and soon led to consolidation of nearly all of the upper lobe on the right side while the middle lobe remained free. On the sixth day sudden and violent pleuritic pain developed on the left side, low down, followed by rapid consolidation of the lower lobe, extending upward and producing complete consolidation of the entire lung. Deep jaundice developed on the sixth day and the urine showed the following changes:

January 12, 1890. Acid, 1031. No albumin, sugar, or casts. *Evening*—Acid, 1027. No albumin, sugar or casts. Many triple phosphate crystals.

15th. Acid, reddish color, 1024. Distinct amount of albumin. No sugar. No casts. No red blood-corpuscles. Teichmann's crystals.

16th. No hæmin crystals. Bile pigment detected by Gmelin's test.

17th. Acid. Trace of albumin. Bile pigment. No sugar. No casts. A few bile-stained leucocytes.

There were no cerebral symptoms, but a most singular persistence of a feeling of comfort, of strength and of improvement within a few hours before death; with a perfectly clear mind and a natural tone of voice he asserted that he felt well enough to sit up and walk across the room. The temperature rose progressively to 105°, the respirations steadily grew more rapid up to 50 to 60, and the pulse lost strength and grew very rapid. There was increased cyanosis. He died of heart-failure on the beginning of the eighth day. No microscopical examination of the sputa was made. The autopsy showed typical croupous consolidation of the entire left lung and, on the right side, of the entire lower lobe

and of scattered patches in the apex. The middle lobe remained entirely free but was not fully expanded. The bronchial tubes were not obstructed; on both sides there were layers of plastic lymph; there was no pericarditis; no ante-mortem clots or valvular lesions. The liver was stained yellow, its tissue presented no marked change to the naked eye and the bile-ducts seemed pervious. No lesions of the gastro-intestinal canal. The blood seemed somewhat more liquid than normal.

Albumin in the urine was, I think, found in nearly all cases of pneumonia where it was carefully looked for, though not rarely there were no casts. Both hyaline and epithelial casts were found in some cases as early as the second day. It is clear that infectious nephritis was a frequent complication of influenza and especially in cases with pneumonia.

Many cases of pneumonia were associated with an unusual degree of gastro-intestinal irritability. Vomiting frequently occurred spontaneously at the onset and was readily caused by food or medicines during the course of the disease. Diarrhœa was also often easily caused. Both of these symptoms were highly unfavorable. Hæmorrhage from the bowels occurred in one case which came under my observation where there had been marked abdominal distress and fulness. A case is quoted here in full not only on this account but as illustrating peculiar physical signs and nervous symptoms.

CASE II.—Mr. X., aged forty-six, of excellent health, but probably somewhat overtaxed and depressed in vitality, having recently suffered from a very severe carbuncle, had a sharp attack of influenza. His whole family suffered at the same time. He went out and attended to business while still relaxed and with a hard, dry cough. He exposed himself on the evening of January 8th, going out in a damp, raw air and was attacked about midnight with chills, violent pains on the right side of chest, cough, and rapid development of fever. On physical examination there was found an extraordinary weakness of respiratory murmur over the right lung, especially over the two lower lobes. It was scarcely possible to hear the vesicular murmur, and crepitant râle was developed only after cough. Even on the left side there was no compensatory exaggeration of the respiratory murmur. The case developed into typical lobar pneumonia, involving the entire posterior part of the right lung and the anterior part of its lower lobe. There were a few râles at the base of the left lung, but no pneumonia developed there. The temperature never became very high (103°, maximum). The tongue was heavily coated and the stomach was very sensitive, but he was doing apparently well when there occurred sudden collapse with marked heart-failure and abdominal distress, which was explained soon after by several bloody discharges from the bowels. There had been a great deal of hebetude and mind-wandering before this, and this increased greatly after the pain extended, so that he was desperately ill until the twelfth day, after which improvement began and increased steadily until recovery. The urine showed:

January 10, 1890. Acid, 1018. Marked amount of albumin. No sugar. No casts.

11th. Acid, 1021. Marked amount of albumin. No sugar. No casts.

13th. Acid, 1018. Marked amount of albumin. No sugar. One hyaline and one epithelial cast in three slides.

15th. Acid, 1017. Marked amount of albumin. No sugar. No casts.

The pyrexia deserved more critical study than could be given, owing to the excessive pressure of work. I would observe, in the first place, that there seemed to be a highly pyrogenic state of the system widely prevalent throughout the community during the season. I am sure that such observations as the following must be familiar to all: One of my own children, aged five, seemed somewhat dull late in the afternoon, but did not appear at all unwell otherwise. I found his temperature 104°. In the case of a child, aged twelve, whose mother is a trained clinical observer, but who merely remarked that the child seemed feverish and dull, but did not need any attention, I found the temperature 105°. The pyrexia subsided in thirty-six hours with a development of no local lesion or the evidence of a specific influenza. Naturally, therefore, hyperpyrexia would be expected in complicated cases of influenza, and very many records have been furnished supporting this view. A striking phenomenon was a very rapid rise of the temperature at the commencement of the disease; and not rarely, this initial rise continuing for the first eighteen or twenty-four hours, was followed by a distinct drop with no subsequent rise equal to the initial temperature. Temperatures of 105° and 106°, and in two cases of 107°, have been reported, the latter occurring toward the fatal close of the cases, one of whom was quite clear in his mind and the other fairly rational. On the other hand, in a few cases strikingly low temperatures were noted throughout the course of the extension of croupous pneumonia. In a case involving all of the left lung except the tip of the apex, and terminating in abscess, the initial temperature reached 102° for a brief period, but at no subsequent time was it above 101⅖° until hectic fever set in. It is proper here to call attention strongly to the fact that the vast majority of pneumonias occurred as a sequel, rather than a complication, and that they were clearly traceable to exposure to damp and raw weather while the patient had a relaxed system and while slight pyrexia persisted after the subsidence of the more marked symptoms of his influenza. Experience furnishes many instances of this fact. Both the cases above quoted are striking examples. It was not even necessary that the patient should leave the house to meet with this fate. In a marked case which I saw, a man aged thirty-five, heavily taxed with important professional work and depressed by the loss of a favorite child of three with apex pneumonia of a cerebral type, had an ordinary influenza, from which he improved so greatly by the fourth day that, in opposition to his physician's orders, he rose, dressed, and went to his library at some distance from his bed chamber. He soon had a chill, followed by temperatures of 105° and 106°, with right-sided pneumonia, rapidly developing delirium and deepening stupor, and with rapid and furious convulsions before death, which occurred on the fourth day. The practical lesson taught to all of us by this case must be embodied impressively in the records of this epidemic, and in all future cases of influenza must serve as a most important guide in the management of this disease, especially in this state of convalescence.

Allusion has already been made to the nervous and cerebral symptoms attending the influenza pneumonia of this past season. I am not aware that the cases of pneumonia which occurred unassociated with influenza presented any marked peculiarities in this respect, but, as should naturally be expected, the pneumonias which occurred during or after influenza proved otherwise. In the first place they were often associated with exceptionally severe pain about the chest and with pains in different parts of the body. There is much evidence to show that these pains might be considered partly due to general neuritis or perineuritis of varying degrees of intensity. It is not now the time to discuss the question whether this affection of nerve-trunks was of purely infectious origin or was due to atmospheric influences acting upon systems relaxed and sensitive to an almost unprecedented degree. It would seem, however, that the view of its infectious origin is strongly supported by many facts. The existence of such neural trouble has been made clear in a number of cases by muscular and sensory sequelæ. I refer to it partly in this connection because it has seemed probable to others besides myself that such a condition of the intercostal and respiratory nerves, and possibly of the pneumogastrics themselves, may be invoked to explain not only the chest pains, but the extraordinary weakness of the respiratory murmur noted in so many of our pneumonia cases. Another explanation of this striking phenomenon that has been advanced is the hypothetical enlargement of the bronchial glands. I do not know anything in direct evidence in support of this view, but merely mention as of interest in connection with the matter that Dr. John Todd, of Pottstown, Pa., reports to me that in the cases of influenza occurring in that town there was diffuse enlargement of the lymphatics, even advancing to suppuration. We had no such reports from Philadelphia.

The cerebral symptom which attended the pneumonias here were dulness, at times amounting to deep hebetude, or, in the latter stages of fatal cases, coma. In the following case (Case III.) this type of stupor was strongly marked for two days prior to the clear development of physical signs of consolidation. I am doubtful whether the case was one of influenza at all. It is more probable that it was a typical example of the ordinary infectious type of pneumonia, where, as is well known, the constitutional symptoms may precede by hours or even several days the development of the local lesions.

CASE III.—H., aged twenty-two years, an athlete in splendid condition, though overworked and exposed in a malarial district. He had felt unwell for several days but continued at business. On Friday, December 6th, he felt very tired in the evening, but put on evening clothes and went to the theatre with only a light overcoat. He had fever during the night and slept badly, but rose the following morning and went three miles to work, walking one and one-half miles. He had to go home, however, had a hard chill, and when seen that evening had a temperature of $104\frac{3}{5}^{\circ}$ with evident congestion of the upper lobe of the right lung. He was stupid and heavy, but had scarcely any cough and made no complaint of pain, other than a slight soreness about the right nipple. Consolidation of the right upper lobe was not evident until December 9th. The temperature reached 105° on the second day and for five days remained between 103° and 104°. It began to fall toward the close of the seventh day and by the morning of the eighth day had reached normal. He continued in a state of deep hebetude until the sixth day, but without delirium. Throughout the whole course of the case there were only two slight coughing spells, and only on the fifth day did he raise any sputa and then but two small portions of viscid, rusty-colored exudation. A careful microscopical examination of the blood showed no plasmodium. The entire upper lobe of the right lung and part of the back of the middle lobe were solid. When the temperature fell there was rapid resolution, with complete absorption without any expectoration. There was abundant herpes at both corners of the mouth. He took 10 grains of quinine the first day and on the second day he took 20 grains in one dose in the morning. The stomach then became irritable and he was treated with carbonate of ammonium, 5 grains every three hours, and antipyrine and sodium salicylate, 4 grains each about three times daily. On the seventh day he took five doses of 5 grains of quinine each. The rapid fall in temperature which followed on the next day was probably in large part a coincidence. Quinine was continued in decreasing doses. He made a complete and rapid recovery. The urine contained albumin but no casts. Chlorides were present on every examination.

Delirium was frequently met with and varied much in type and degree. In many cases there was continual mind wandering and delirium, and such cases were not rarely followed by emotional sensibility and weakness. Another type was of wild and maniacal delirium. This came on in some cases at an early stage, even as an initial symptom; it was sometimes persistent, and in not a few cases there was subsequent temporary dementia. Lastly, in other cases, especially in neurasthenic females or in anæmic and exhausted males, there was an excited delirium with garrulousness and even with hysteroidal phenomena. In other cases there was evident irritation, meningeal or cerebral, with wild excitement, passing into stupor with convulsions; or spinal, with stiffness and retraction of the head, muscle-soreness and hyperæsthesia.

Finally, in regard to thoracic symptoms. Cough was at times almost or entirely absent (of course, generally in cases where cerebral symptoms were present). In some instances it was almost suppressed, with no adequate cerebral symptoms to explain it. Ordinarily it was a marked symptom and often severe, paroxysmal, and painful in both croupous and catarrhal forms. I regret to say that there seem to have been in Philadelphia very few careful microscopic or culture studies of the sputa; in the cases where search was made, the pneumococcus is reported to have been found. I am unable to report any new facts in regard to the pneumonic lesions. Certainly in such cases as the first, above reported, the lesions present were to all appearance the typical ones of croupous pneumonia, and the same statement is made of other cases with and without microscopic examination.

There is nothing especial about the sputum except that in cases with little or no cough even extensive consolidation terminated in rapid absorption without expectoration (as in Case III.).

The physical signs were deeply interesting and in many cases were difficult to understand. To such an extent was this the case that I doubt not that in many examinations the diagnosis as to the extent and nature of pneumonia, or even as to the existence of pneumonia at all, was erroneous. The most evident cause of this difficulty was the excessive weakness of the respiratory murmur as above mentioned, and the poor development of all auscultatory phenomena. Further, the co-existence of bronchial catarrh, even in croupous cases, often complicated the physical signs, and not only were the breath-sounds weak in the early stages of congestion, but with complete consolidation the bronchial breathing was at times imperfectly developed.

A careful observer reports that he deliberately punctured a case of croupous pneumonia to establish a differential diagnosis because the bronchial murmur was so feeble as to justify the suspicion that there might be a considerable amount of fluid. Although in many cases of the croupous type there was typical crepitus, it was often developed only on the deep breathing following coughing. In most cases, also, the râles were coarser and heard somewhat in expiration, though chiefly in inspiration, and in cases which were clearly croupous. After the exudation was absorbed, the affected area continued in some cases for a considerable time to give impaired resonance, weak breath-sounds, and fine expansion crepitus.

CASE IV.—Mrs. W. was seen in consultation with Dr. James Collins. She was a woman in good general health when she was attacked with a slight chill, followed by fever and coughing, which soon became associated with some pain, especially in the right side. There were also pains throughout the body evidently due to influenza. The fever was of the regular type, with a maximum of $104\frac{3}{5}°$ and with daily variations of from 2° to $3\frac{1}{2}°$. At the close of the fourteenth day the temperature reached 100°, but did not remain down long as symptoms of increased pulmonary trouble in the form of catarrhal pneumonia developed, and for the next five days the fever ranged between 100° and 103°, dropping again on the seventeenth day to $99\frac{2}{5}°$. The next two days presented an even greater range of remission from 104° to $99\frac{2}{5}°$, and the following day rose from 100° to $104\frac{2}{5}°$; from the eighteenth day to the twenty-eighth day the fever ranged from 103° to 105°, reaching $105\frac{1}{5}°$ once. It then gradually fell and reached 99° on the thirtieth day, and during convalescence did not again rise above 100°. From the thirteenth day to the thirtieth day the patient was so ill that her life was despaired of. Both lungs were extensively involved, but at no point was there any considerable area of dulness. The respiratory murmur was extremely feeble and in many places almost inaudible. At other points it was feebly blowing, with prolonged expiration. Percussion resonance on very light percussion gave very irregular results at different points of the pulmonary area. The cough was feeble and there was very little expectoration. It was not rusty-colored at any time. The pulse was extremely feeble and ranged from 96 to 136. The râles heard were irregularly distributed and at certain points, both anteriorly and posteriorly, there were quantities of small subcrepitant râles. The respirations were not very rapid in comparison with the temperature, the average being from 24 to 26 in a minute. The treatment consisted of nutritious enemata, small doses of morphine with quinine by suppositories, and by the mouth strychnine in large doses with aromatic spirits of ammonia. The patient made a complete recovery.

It is not designed to make any remarks in reference to treatment. The general type of the disease forbade the use of depletives or of depressing remedies. The general course of treatment which seems most useful may be inferred from the cases above reported.

ORIGINAL ARTICLES.

ON THE RADICAL CURE OF HERNIA, WITH RESULTS OF ONE HUNDRED AND THIRTY-FOUR OPERATIONS.[1]

BY WILLIAM T. BULL, M.D.,
SURGEON TO THE NEW YORK HOSPITAL; PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

AT the meeting of last year this Association had the benefit of a thorough critical paper on the various methods of radical cure of hernia, from Dr. Mastin, who used these words in closing the discussion: "But at this date the operation which is best calculated to offer general satisfaction remains a mooted question, and until more accurate experience decides it, the selection of the special operation must still remain *sub judice*." It goes without saying, that in the solution of this problem, "accurate experience" is not the only desideratum. Observations which cover a number of years are equally important. The tendency of hernia to relapse after apparent cure was a well-established fact when mechanical treatment was the general rule of practice, and, except in the case of children, patients were encouraged after the hernia ceased to appear, to continue the use of trusses as a safeguard against relapse. In illustration of this fact Segond,[2] in his thesis on "Radical Cure," presents a table of 39 cases, collected by Berger, in which, after apparent cure by the truss, relapse was noted at periods varying from five to sixty years.

But in the commendable zeal to perfect some method of cure for this disabling conditions, operators seemed to have overlooked this tendency to relapse, and have been ready to propose one modification after another, with a confidence justified by only months of observation. Even since the experience of surgeons has shown that the majority of relapses occur within a year after radical operation,[3] there have been plenty of new methods, or justifications of older ones after a brief period of waiting.

As an illustration of this undue haste in forming conclusions, I may refer to a paper read before a

[1] A paper read at the meeting of the American Surgical Association, at Washington, May 14, 1890.

[2] Cure Radicale des Hernia, p. 350. Paris, G. Masson, 1883.

society in New York, during the past winter, in which the writer reported, as cured, some cases operated on within a year, by the "open method," approved by McBurney, with some personal modifications. In less than three months later, three of the patients were reported to the surgeon from the Hospital for Ruptured and Crippled, as having applied for trusses for the relapsed herniæ. I was, myself, an example of this short-sightedness when, in 1882, I reported to the Surgical Society of New York, 5 cures in 21 cases of reducible hernia, by Heaton's method of injection, the oldest having been observed for one year and nine months only. Within the next year all these cases relapsed.

The difficulty of tracing patients after their discharge from hospital or private treatment has undoubtedly much to do with the incompleteness of the evidence offered in support of different procedures. A patient, who at the end of a few months is known to have no relapse, is counted as cured; if he then disappears the record is completed, and he stands as a "cure," of equal significance with one which has been examined after a much longer period of observation. The number of such cures, the continuance of which varies greatly, is a prominent factor in estimating the value of any method. This is not the accurate and continued observation which is needed.

It will be of decided advantage in comparing methods in the future, if we discard altogether the word "cure," and estimate their relative merits by a statement, first, of the total number of operations with result as to recovery, wound-complications and healing, then by an enumeration of the cases which have been examined at later periods with the proportion of relapses.

It is in accordance with these considerations that I present the results of my own work during the past seven years. In many respects the data are not so complete as they ought to be; but this shortcoming seems unavoidable in work done, as this has been, in four different hospitals, with a constantly changing staff of internes. After the injection treatment (Heaton) proved so unsatisfactory, I took up in 1883, shortly after the publication of Leisrink's statistics,[1] the more modern methods. An examination of the methods on which Leisrink reported, satisfied me that the most essential feature of any effective procedure was that proposed by Riesel, viz., the ligature of the sac at its highest point. This has since been generally adopted. But there was some doubt in my mind as to the relative advantage of the closure of the pillars of the external ring with sutures, proposed by Czerny, or the plan adopted by Socin, of merely leaving the canal to granulate over the sutured integuments. In the first series of cases, 40 in number, I followed this plan. After exposure of the neck of the sac, by dividing the integuments and anterior wall of the inguinal canal, the sac was isolated and ligated at its neck with catgut; the portion below was dissected out when it was small; when large, or containing the testicle, it was merely drained through the bottom of the scrotum. The wound was sutured over a drain in the inguinal canal, which was left for three or four days. This method, which may for brevity be termed the method of "ligature and excision of the sac," has been adhered to and favorably reported on by Socin,[1] of Bâle.

In a second series of cases, 39 in number, the method has been the same with the addition of catgut sutures to the pillars of the external ring and the divided aponeurosis. This may be denominated the method of "Ligature, excision, and suture." It is Czerny's method with the addition of the high ligature of the sac, as Riesel proposed, and has been extensively employed by Banks, of Liverpool,[2] who, however, used silver wire for suture.

I compared these two methods in a paper before the New York State Medical Association, in September, 1889, and found that, estimating the "cures" and relapses in accord with the plan adopted by others, the results were almost identical. Twenty patients in each series had been followed for periods varying from six months to four years; forty per cent. had relapsed, and sixty per cent. were "cured" when heard from. All of these patients had been operated on more than one year previously, but some of them could not be found at a later period than a few months after operation. I have subjected these patients to a fresh scrutiny,[3] in the past three months, with the help of Dr. Albert H. Leyton, and, as will be seen later, more time having elapsed, the percentage of so-called "cures" has suffered no diminution.

The third series embraces 39 cases, all operated on in 1889; in these the sac had been treated as before, but the anterior wall of the canal has been more respected and only divided when it was impossible to reach the neck by drawing down the sac. But the canal has been sutured with two layers of silk or catgut sutures, the deeper ones uniting the muscular fibres, the more superfical ones the aponeurosis and the pillars of the external ring. I would call this the method of "Ligature, excision and suture of canal."

The fourth series consists of sixteen operations

[1] Die moderne radical-operation des unterleibsbruches. Hamburgh, Leopold Foss, 1883.

[1] Revue de Chirurgie, April 10, 1888, 264.

[2] British Medical Journal, December 10, 1887.

[3] In rearranging these cases, one case has been lost from the second series, making the number now 39 instead of 40, as before reported.

on children, between the ages of four and fourteen. Here no one method has been adhered to because the condition of the herniæ varied greatly. All operations have been performed within the past six months, but enough relapses have been noted within that time to warrant some conclusions.

The total number of cases may be advantageously considered with reference to indications, mortality, complications, and wound results. As to indications, of the 134 cases, 77 were reducible, 42 irreducible, and 15 strangulated. In nearly one-half, then, the radical cure was added to the operation for the relief of irreducibility or strangulation. This is in accordance with the general belief, I think, that it should be done in such cases with few exceptions. In irreducible herniæ I would except only scrotal enteroceles of long standing and voluminous contents, where the adhesions between loops of intestine are firm, and the return of the long-protruded mass is sure to be a matter of difficulty. It necessitates a prolonged operation with much bleeding and many raw surfaces, and the aperture is sure to be large and little likely to be closed long by any method of suture. In general, I believe that irreducible cases are best treated by operation; they do not bear the pressure of any truss with comfort, and are constantly liable to have fresh contents descend into the sac. It must be remembered, however, that many small irreducible ruptures, both inguinal and femoral, of a few days' duration, will undergo spontaneous reduction by rest in bed, or even while on the feet, with the pressure of a spica bandage.

In strangulated hernia, when the gut is not returned, the radical cure must naturally be omitted. When patients are too feeble to warrant any prolongation of the operation, it is undesirable.

Of the reducible cases, the majority have presented difficulties in the management of a truss, or, in a few instances, have been anxious to try the radical cure as a means of dispensing with it, or of being able to wear one with lighter pressure. There have been more of these cases in the third series, as shown by the following table:

Series.	Reducible.		Irreducible and Strangulated
I. contains	11	and	29
II. "	21	"	18
III. "	29	"	92

All the cases in Table IV. have been reducible.

At the outset of my experience, I was disposed to operate without regard to age. The first series shows in regard to age:

2 patients under 20
6 patients from 20 to 30
10 " " 30 " 40
8 " " 40 " 50
9 " " 50 " 60
5 " over 60

Of these 40 patients, the earliest operated on, 14 were over 50. In the second series there were but 5 over 50, as I had begun to think it undesirable to attempt the radical cure at this age, unless in connection with irreducible or strangulated cases. The ages in Series II. are:

2 patients under 20.
12 patients from 20 to 30.
7 " " 30 " 40.
11 " " 40 " 50.
4 " " 50 " 60.
1 patient over 60.
2 patients not given.

In the third series of cases, the ages are about the same as in the second. The fourth series of patients were all between the ages of 4 and 14. The indication for operation was either difficulty of retaining the rupture with a truss, or absence of any improvement in its condition as the child continued under observation. In one or two instances, inability of the parents to adjust the truss, or inattention or irregular attendance constituted impediments to the mechanical treatment. In one instance, an adherent appendix, in another a thin slip of adherent omentum, in a third a testicle arrested in the canal explained the difficulty of retention.

There are three deaths in the entire number of 134 cases, two in the first series and one in the second. The third and fourth lists represent 55 cases in succession with no fatal result. The first death was (Case 5, Table I.) a man of eighty, in apparently good health, who was subjected at the same time to the radical operation for hydrocele (Volkmann's) on the opposite side. The hernia was a large, scrotal entero-epiplocele, and a portion of omentum was excised after ligating. Death resulted in twenty-four hours from the shock of slight hæmorrhage into the peritoneal cavity from an atheromatous artery in the omentum, which had been cut by the ligature. The second fatal result was in a healthy patient (Case 26, Table II.), twenty-six years of age, whom I advised to undergo the radical operation for an irreducible epiplocele; a large bunch of omentum was removed after ligating with great care, the attention of those present being called to the advantage of using heavy silk for this purpose. Bleeding occurred after the stump was replaced in the cavity; a large incision was necessary in order to withdraw the omentum and re-ligate the vessels. The ligature had slipped. The cavity was cleansed of blood and no further oozing took place, but death resulted from septic peritonitis in twenty-four hours. The third death (Case 15, Table II.) was from shock in a large, scrotal strangulated case of twenty-four hours' duration.

These fatal results are worthy of notice in so far as they serve to emphasize my conviction that old and feeble subjects should not be subjected to opera-

tion in reducible cases, and that too much attention cannot be given to management of the omentum. In cases of strangulated hernia the radical measures should be omitted, if patients are not in condition to endure safely prolongation of the operation.

The complications existing at the time of operation were a large uterine fibroid in one case, hydrocele of the tunica vaginalis in three cases. The latter condition was managed simultaneously by simple drainage with good results.

In the course of the operation there was bleeding from a faulty ligature in one case (ending fatally, as just mentioned), wound of the intestine in four instances, and division of the vas deferens in one case. The intestinal wounds were all made in separating adhesions; all were promptly sutured and no accident resulted. In one case there were five tears made in separating intestine from the wall of a suppurating sac (an irreducible case, 34, Table I.). The wounded vas deferens was not sutured; suppurative orchitis followed, with burrowing of pus in the abdominal wall. The patient was a healthy farmer, forty-seven years of age, and was eighty-five days under treatment. There were no accidents or complications among the children.

Following the operation, the general complications to be noted are acute mania in a woman sixty-eight years of age, who could not be traced after removal from hospital (Case 4, Table I.), and erysipelas in one case, which developed from a slowly healing sinus. Septic fever has been so exceptional as to be hardly worth noting, though the wounds have healed primarily in only about one-half the cases, as the following table shows:

Series.	Prim. union.	Suppur.	Died.	Not stated.
I.	16	21	2	1
II.	21	16	1	1
III.	12	14	0	13
	49	51		

IV. All wounds healed primarily but one; this was in an unruly boy of defective intellect who tore off his dressings.

By primary union is meant the occurrence of prompt healing of the wound which, with the exception of the drainage-tube opening, has closed within a few days with but a few drops of pus. Many of the cases noted as healing by suppuration were simply slow-healing drainage openings. Profuse suppuration has been rarely noted. Of the adult cases the duration of treatment on the average was 26½ days, the shortest being 10, and the longest 85 days. Bichloride irrigation and moist dressings have been uniformly employed; drains were of rubber (a few of glass); catgut was prepared according to Kocher's formula with oil of juniper.

My practice has been to make the first dressing at the end of two or three days for the purpose of removing the tubes, and to permit the second dressings to lie in place a week, if no complication occurred. Silk was used for buried sutures in about a dozen cases, boiled in five per cent. carbolic acid solution immediately before and sometimes during the operation; yet in spite of these precautions, all the cases heard from had small abscesses after leaving hospital and discharged one or more sutures.

Of the varieties of hernia, there were 116 inguinal, 15 femoral, and 3 ventral. In the different series there are reported as follows:

	Series I.	Series II.	Series III	Series IV.
Inguinal.	26 { 9 reducible. 13 irred. 4 strang.	36 { 22 reducible. 11 irred. 3 strang	38 { 28 reducible 6 irred. 4 strang.	16 reducible.
Femoral.	12 { 1 red. 7 irred 4 strang.	2 irred.		
Ventral.	2 reducible.	1 irreducible.		

The subsequent observation of these patients gives the following results as to relapse:

Of the 40 cases operated on in the first series, by the method of ligature and excision of the sac, only 22 have been traced:

	Total Number.	No Relapse.	Relapse.
Cases under obs over 5 years	1	1	0
" " " from 4 to 5 years	3	3	0
" " " " 3 " 4 "	2	1	1
" " " " 2 " 3 "	0	0	0
" " " " 1 " 2 "	9	8	1
" " " less than 1 year	7	1	6
	22	14.	8

Of the 39 cases operated on by the method of ligature, excision and suture of the external ring, but 20 have been traced, with this result:

	No Relapse.	Relapse.
Under obs. from 3 to 4 years 1	0	1
" " " 2 " 3 " 4	3	1
" " " 1 " 2 " 10	8	2
" " less than 1 year 5	1	4
20	12	8

Of the 39 cases operated on by the method of ligature, excision and suture of the canal and external ring, 20 have been followed for less than one year with the result that 11 have recurred.

Of the 16 children, all operated on within a year, 5 have already presented relapses — at the end of one month in 2 cases, two months in 1 case, three months in 1 case, and four months in 1 case. In 6 patients, the sac was cut across just below its neck, the remainder drained and the canal sutured. But 1 of these herniæ has reappeared as yet. In the 10 others, all small, the sac was not found, and the pillars of the external ring were sutured: 4 of these have relapsed.

In comparing these methods, without reference to the time of observation, we find that:

By method I., ligature and exision of sac, there are 36.36 per cent. of relapses in 22 cases.

TABLE I.—CASES OPERATED ON BY LIGATURE AND EXCISION OF THE SAC (SOCIN).

No.	Sex.	Age.	Variety and duration	Date. Complication.	Result.	Duration of treatment.	Last observation.
1	M.	30	Inguinal.	April 8, 1883; omentum removed.	Recovered	30 days.	
2	M	32	Strangulated inguinal, few hours. Hernia 12 years.	August 13.	Recovered	10 days; primary union	July, 1889. No relapse Truss.
3	F.	55	Irreducible inguinal, 3 years. Small.	March 3, 1884, omentum removed.	Recovered	53 days.	
4	F.	58	Strangulated inguinal, 2 days. Hernia 30 years.	May 25; insanity developed.	Recovered	12 days; primary union.	
5	M.	80	Double inguinal, right, 25 years; left, 3 years. Left hydrocele radical cure at same time.	July 7, omentum removed. Hæmorrhage into peritoneal cavity.	Died		
6	M.	40	Inguinal. Small.	September 11.	Recovered	15 days, primary union.	
7	M.	5	Irreducible inguinal, 4 mos. Small.	October 27; omentum and appendix removed.	Recovered	12 days; primary union.	February, 1886. Died. No relapse at time of death.
8	M	46	Inguinal, 14 years. Herniotomy 4 years previous. Hernia returned in 2 days. Large.	November 6; omentum removed.	Recovered	18 days; primary union.	May, 1889. Relapsed three and a half years later.
9	F.	48	Irreducible femoral, 3 years. Small.	December 9; omentum removed.	Recovered	37 days.	July, 1886. No relapse. No truss.
10	F.	51	Irreducible femoral, 8 months.	December 10; omentum removed.	Recovered	42 days.	
11	M.	55	Inguinal, 8 years. Large.	January 21, 1885.	Recovered	57 days.	
12	F.	61	Strangulated femoral, 8 days. Hernia 10 years.	January 23.	Recovered	31 days.	August, 1886. Relapsed. Truss.
13	F.	38	Strangulated femoral Hernia 3 years.	January 29.	Recovered	21 days.	July, 1886. Relapsed soon afterward. Truss.
14	M.	23	Strangulated inguinal, 12 hrs. Hernia 5 years. Radical cure 1 year ago No relapse until 12 hours previously.	February 15.	Recovered	46 days.	January, 1886. No relapse. No truss.
15	M.	35	Irreducible inguinal, 15 years.	March 9, omentum removed.	Recovered	20 days; primary union.	
16	F.	43	Irreducible femoral, 5 years.	June 29; omentum removed.	Recovered	32 days.	July, 1886 No relapse. Truss for nine months.
17	M.	18	Irreducible inguinal, life time Small.	June 30; omentum removed.	Recovered	34 days.	
18	F.	49	Irreducible inguinal, 6 years. Small. Fibroid of uterus.	July 27.	Recovered	59 days.	
19	M.	31	Irreducible inguinal, 5 years. Very large.	August 4; omentum removed.	Recovered	55 days.	January, 1890. No relapse. Truss.
20	M.	39	Irreducible inguinal, 15 years. Large. Strangulation reduced by taxis.	August 13.	Recovered	39 days.	
21	M.	28	Inguinal, 3 years.	August 25; omentum removed.	Recovered	13 days; primary union.	January, 1890. No relapse. Truss for two years.
22	F.	29	Femoral, 2 months. Small.	September 18.	Recovered	12 days; primary union	January, 1890. No relapse. No truss.
23	M.	23	Inguinal Small.	November 17; omentum removed.	Recovered		
24	F.	61	Irreducible femoral.	January 16, 1886; omentum removed.	Recovered	Primary union.	
25	F.	60	Strangulated femoral, 3 days. Hernia 3 years.	June 16; omentum removed.	Recovered	12 days; primary union.	
26	M.	36	Irreducible inguinal, 5 years.	August 3; omentum removed. Hæmorrhage from stump in peritoneal cavity. Stump drawn out; vessel tied.	Died	.....	Autopsy. Septic peritonitis.
27	M.	71	Strangulated inguinal, 12 hrs. Hernia 12 years.	September 5; omentum removed.	Recovered	31 days.	January, 1890. No relapse. No truss.
28	M.	29	Irreducible ventral, 5 years. Small.	March 16, 1887; omentum removed.	Recovered	16 days; primary union.	
29	M.	20	Inguinal, 8 months. Small.	May 11; omentum removed.	Recovered	42 days; primary union	
30	M.	46	Ventral, 12 years. Small.	July 14; omentum removed.	Recovered	38 days.	January, 1889. No relapse.
31	M.	59	Irreducible inguinal, 20 years	September 2.	Recovered	25 days; primary union.	Relapsed in one month.
32	M.	35	Inguinal, 16 years.	May 15, 1888, omentum removed.	Recovered	51 days.	January, 1890. No relapse. No truss.
33	M.	20	Irreducible inguinal, 5 years.	May 19, omentum removed.	Recovered	24 days.	January, 1890. No relapse. Truss Hernia on opposite side.
34	M.	47	Irreducible inguinal, 4 years. Hydrocele.	June 5; abscess of omentum and sac; intestines wounded. Drainage of abdominal cavity.	Recovered	38 days.	October, 1888. Relapsed. No truss.
35	F.	37	Strangulated femoral, 24 hrs. Hernia 6 years.	July 14; omentum removed.	Recovered	13 days; primary union.	January, 1890. No relapse. Truss.
36	M.	55	Irreducible inguinal, 4 days. Small	July 18; omentum removed	Recovered	85 days.	January, 1890. Relapse.
37	F.	76	Irreducible femoral, 13 years. Small.	July 26.	Recovered	18 days.	January, 1889. Relapsed. No truss
38	M.	51	Irreducible inguinal, 35 years.	September 3; omentum and appendix removed.	Recovered	28 days.	August, 1889. Relapsed.
39	F.	60	Irreducible femoral, 4 years.	September 15; omentum removed.	Recovered	17 days; primary union	
40	F.	49	Irreducible femoral, 6 months. Small.	December 7; omentum removed.	Recovered	11 days, primary union	January, 1890. No relapse.

TABLE II.—CASES OPERATED ON BY LIGATURE AND EXCISION OF SAC, WITH SUTURE OF EXTERNAL RING (BANKS).

No.	Sex.	Age.	Variety and duration.	Date. Complications.	Result.	Duration of treatment.	Last observation.
1	M.	14	Inguinal. Small.	June 1, 1885; omentum removed.	Recovered	19 days; primary union.	July, 1886 Relapsed. Truss.

27	M.	26	Irreducible inguinal, 2½ yrs.	June 23; omentum removed.	Recovered	18 days; primary union.	January, 1890. No relapse. No truss.
28	M.	45	Inguinal, 10 years. Large.	June 25.	Recovered	24 days; primary union.	
29	M.	24	Irreducible inguinal, 2 years.	July 16; omentum removed	Recovered	28 days.	
30	M.	23	Irreducible inguinal, 8 years.	August 4; omentum removed.	Recovered	16 days; primary union.	January, 1890. No relapse. No truss.
31	M.	55	Irreducible ventral, 4 years. Small.	August 27; omentum removed.	Recovered	10 days; primary union.	January, 1889. Relapsed.
32	M.	38	Inguinal, 7½ years. Large.	September 1.	Recovered	41 days.	January, 1889. No relapse. Truss.
33	F.	20	Inguinal, 18 months. Small.	December 13.	Recovered	10 days; primary union.	
34	M.	36	Inguinal (left), 10 years.	December 20.	Recovered	25 days.	
35	...	...	Inguinal (right), 1 year.	December 20.	Recovered	25 days; primary union.	
36	M.	46	Inguinal (right), 6 months.	December 20.	Recovered	12 days.	January, 1890. No relapse.
37	M.	30	Irreducible inguinal, 2 years. Hydrocele.	December 24.	Recovered	15 days.	
38	M.	59	Irreducible inguinal, 39 years.	December 27.	Recovered	30 days.	
39	F.	31	Irreducible femoral, 8 years	January 2, 1889.	Recovered	15 days; primary union.	January, 1890. No relapse. No truss.

By method II., ligature and excision of sac, and suture of external ring, there are 40 per cent. of relapses in 20 cases.

This is a very trifling difference, and seems to my mind to prove that there is little choice between the two procedures. The first method has been the longer on trial by two years. It is simpler and more rapidly executed.

But the results of the first two methods are about the same, when the period of observation is taken into account. Of the cases under observation for less than a year, six out of seven relapsed in the first,

39	M	21	Inguinal, 18 months.	December 28	Recovered	10 days; primary union.	

Table IV.—Cases of Hernia in Children Operated on at the Hospital for Ruptured and Crippled 1889–90.

The duration stated by parents is of doubtful value: all the cases where sac was found were anatomically congenital, except one.

No.	Sex.	Age.	Variety and duration.	Date. Complication.	Result.	Duration of treatment.	Last observation.
1	M.	6	Congenital, inguinal, scrotal; difficult.	December 3, 1889. Suture of ring. Sac not found. Wound closed; no drain.	Recovered	Primary union.	Relapsed in scrotum at end of one month. Truss.
2	M.	8	Incomplete inguinal, 6 mos.?	January 4, 1890. Suture of ring. Wound closed; no drain.	Recovered	Primary union.	Relapsed in 2 months.
3	M.	12	Inguinal, 5 years?	January 7. Removal of sac. Suture of ring: scrotal drain.	Recovered	Primary union.	Relapsed in three mos.
4	M.	7	Inguinal, 2 months?	October 30, 1889. Removal of sac. Suture of ring and canal; scrotal drain.	Recovered	Primary union.	
5	M.	12	Inguinal, 5 years?	January 28, 1890. Suture of ring.	Recovered	Primary union.	
6	F.	13	Inguinal, small, 5 years?	November 12, 1889. Suture of ring.	Recovered	Primary union.	March 8, 1890. Relapsed. Truss.
7	F.	12	Inguinal, 3 years?	October 22. Suture of canal and ring.	Recovered	Primary union.	
8	M.	6	Inguinal, 6 years? Treated twice before; wearing plaster for Pott's disease.	November 19. Excision, ligature, and suture.	Recovered	Primary union	February 27, 1890.
9	M.	9	Congenital, inguinal.	October 30. No sac found. Suture of ring.	Recovered	Primary union	November 25, 1890. Relapsed.
10	M.	13	Inguinal? Small.	November 19. No sac found. Suture of ring.	Recovered	Primary union.	
11	M.	14	Inguinal?	November 12. No sac found. Suture of ring.	Recovered	Primary union.	March 6, 1890. No relapse. Truss in daytime.
12	M.	8	Inguinal, 1 year? Unable to hold.	May 8. Excision and suture; scrotal drain.	Recovered	Primary union.	
13	M.	4½	Inguinal, 4 years?	February 14, 1890. Suture of ring.	Recovered		
14	M.	5½	Inguinal, 1 year?	February 21. Suture of ring.	Recovered		
15	M	10	Inguinal, double, 8½ years.	February 14. Left ligature and suture.	Recovered		
16	M.	13¾	Inguinal, 9 years.	February 21. Excision of sac. Suture of canal. Small hydrocele of cord incised.	Recovered	April 3, suppuration.	

and four out of five in the second. In the second year the proportion of failures is about the same, but it is much less in each. Thus of nine cases operated on by the first method only one, and of ten by the second method only two recurred. In both, the tendency to relapse during the first year is markedly shown, and the inspection of cases traced after two or three years shows a much larger proportion of cases that have not reappared.

A comparison between these two and the third method, ligature, excision and suture of the canal, can be made only roughly by noting the proportion of cases recurring during the first year. This should be compared, however, with the number of cases by the other methods that have been longer under observation. If we do this we find that:

In the first series of 22 cases, 6, or 27.27 per cent., relapsed within one year.

In the second series of 20 cases, 8, or 40 per cent., relapsed within one year.

In the third series of 19 cases, 8, or 42 per cent., relapsed within one year.

If this third method has no better showing in the first year it is not likely that it will after longer observation, and it is not, therefore, entitled to greater confidence.

Of the cases in children it may be said that they prove or disprove nothing; but the prompt recurrence in cases where the sac was not found shows the importance of obliterating it in any method of cure, as well as the uncertainty of simple closure of the pillars of the external ring with sutures.

Of the effect of the use of trusses after the radical operation I can form no positive conclusion. Of the cases which relapsed where this fact was inquired into, six used trusses, three did not. Of those which did not relapse, eighteen wore trusses, eleven used none. I have usually directed patients to wear a very light support, and shall continue to do so. It seems to me important that no strong pressure should be made upon the recently healed parts; but that, on the other hand, they should be supported against the weight of the abdominal contents.

There is no advantage shown by the comparison of these methods in the femoral and inguinal varieties of hernia. If suture of the inguinal canal or the external ring leads to no better result than that of leaving the wound to heal after a drainage-tube, we cannot hope to close the femoral-canal opening any more securely.

In eight femoral herniæ, the method of ligature and excision has given me three relapses, and five apparent cures; while in inguinal hernia there are thirteen cases, eight without and five with relapse.

Of two ventral herniæ, situated between the sternum and umbilicus in the median line, one has recurred, the other has not. Another similar hernia, treated by the same method, the aponeurosis being sutured, has recurred.

Of the ages in reference to relapse, I can merely say that the majority of relapsed cases are over forty.

In reflecting on the experience of these cases I am obliged to conclude that in these methods, which I have faithfully tried, there is no prospect of attaining a radical cure of any form of hernia, and that the majority of cases will be found to relapse, if followed for a sufficient time. I am convinced, however, that the attempt to cure is desirable, since the majority of patients are in better condition than before. This is certainly true of irreducible cases, and of all reducible ones which are subjected to operation because mechanical treatment is difficult or painful. The patient who wears his truss with comfort and safety is only bettered by the operation so long as the rupture remains out of sight. The attempt to cure is furthermore desirable, since it can be made witht rifling risk to life, except in feeble, old, or unhealthy patients, and with little chance of complications or accidents. My own results as to relapse being no better by the complicated method of suture of the ring alone, or of the ring and canal, than by the simpler method of excision of the sac after ligature, I shall confine myself to that method of operation till other procedures, which have stood the test of years, make a more promising showing.

This method has the further advantage of being applicable to all forms of herniæ.

Of the newer operations, of which there are a multitude, I have not been unmindful in framing these conclusions. Each one has its earnest advocate; with a large number of theoretical advantages, or any brief period of observation, I doubt if any, subjected to the same continued scrutiny that my methods have been, will show better results. I am becoming confirmed in that judgment day by day in witnessing the relapsed cases that apply for trusses to the Hospital for Ruptured and Crippled. Between January and October, 1889, there were forty-five such cases, and in the past nine months there have been fully as many more. I am trying to trace the history of all these patients, about 100 in number, in order to obtain accurate knowledge of the methods employed. It will be of interest to know that thus far, of the forty-five patients above mentioned, twenty-two have been thus investigated. Of these, eleven had been operated on by McBurney's method, the shortest period of relapse being one month, the longest eleven months. Two had been subjected to treatment by injection, according to Heaton, with relapse at two months and eighteen months. In four operated on by ligature and excision, recurrence occurred on the average at the end of one year. One, by Macewen's method, recurred in seven months. One relapse took place four years after ligation and excision of the sac with suture of the external ring. Another, five years after treatment, by purse-string suture and inversion of the sac. Two patients, in whom the sac was sutured at its neck, had relapses in four and five months, respectively.

These observations will, without doubt, be duplicated in the cases yet to be traced, and go to strengthen the conviction that all methods of radical cure will be found unsatisfactory.

THE ETIOLOGY OF PLEURITIS, ESPECIALLY IN ITS RELATION TO TUBERCULOSIS.[1]

BY A. A. SMITH, M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE frequent occurrence of pleuritis, its apparent harmlessness in some cases, its very serious character in others, and the great variety of conditions under which it may arise must make it always a subject of interest. Since the discoveries of Koch, and the interest in the whole subject of tuberculosis excited by those discoveries, the study of the etiology of pleuritis and the significance of its relation to tuberculosis have received a new stimulus. Many careful observations have been made and very different conclusions have been reached by observers.

If one follows the discussions of the past few years on the subject of the relation of pleuritis to tuberculosis, he must have been thoroughly impressed with the difficulties of arriving at a satisfactory conclusion. If, as is claimed by many excellent observers, almost all cases of pleuritis not traceable to the ordinarily recognized causes are of tubercular origin, then not only must much more care be given to the diagnosis and probable etiology, but to the prognosis and treatment. If a case of pleuritis, sooner or later, goes on to the development of pulmonary tuberculosis, it is easy to accept the view that the pleuritis was of tubercular origin. The most earnest advocates of the tubercular origin of pleuritis admit that it is very difficult to prove in any given case, unless there is evidence of tubercular lesions elsewhere.

Ehrlich is of the opinion that tubercle bacilli can be demonstrated in all exudations of tubercular nature except the sero-fibrinous.

Fränkel believes it very difficult to discover the bacillus of tuberculosis in the fluids effused into the thoracic cavity, and yet he is of the opinion that

[1] Read before the Association of American Physicians, May, 1890.

the large majority of these cases are of tubercular origin.

Von Ziemssen says that even if it is not possible to show in most sero-fibrinous pleuro-exudates the microörganisms, this is no proof of their non-existence, as they may be lost in the perforation made in the pleura by the exploring-needle, or they may only occur in the form of spores.

From October 1, 1889, to April 1, 1890, I had under special observation, with a view to careful investigation and examination of the pleural exudates and sputa, 9 cases of pleuritis in Bellevue Hospital; 5 of sero-fibrinous exudations and 4 of purulent. The fluids were repeatedly examined, and were taken from the lowest portion of the pleural sac as the situation most likely to contain the cell constituents, if any were present. In not a single instance were any tubercle bacilli found. Likewise the sputa were carefully and repeatedly examined, and in only one instance were tubercle bacilli found and that was in a case in which the exudate was purulent. This was the only evidence of tuberculosis in the case; careful physical examination failed to reveal evidences of pulmonary tuberculosis. In one case of sero-fibrinous exudation the patient was aspirated twice in October. After the second aspiration the patient's condition improved very materially until early in March, when she developed an acute febrile attack with evidences of peritonitis, and died in three weeks. The autopsy was interesting in that it showed evidences of tubercular peritonitis, a tubercular lesion in the left Fallopian tube and a few miliary tubercles on the left pleural surface of the diaphragm. No tubercular lesions were found in the lungs. It was the *right* pleural sac from which the fluid had been drawn in October. These cases are mentioned to show the difficulties in the way of determining the origin of pleural exudates. They are not given as instances of tubercular or of non-tubercular pleurisies.

The study of the results of inoculation of the pleural exudates has been unsatisfactory, at least in so far as the production of tuberculosis is concerned. The most recent observations in this direction have been made by von Ziemssen, who concludes that although fresh pleural exudates injected into the serous cavities of dogs, and into their subcutaneous cellular tissue, has not produced true tuberculosis, they have acted injuriously, "but the infecting potentiality could not be isolated."

It is well known that tuberculous sputa and tuberculous material from the lungs can be injected into the tissues of animals and produce tuberculosis. On the other hand the material from so-called tuberculous joints has only, to a very moderate extent, the power of producing tuberculosis in animals. The potentiality seems to be limited to certain tissues. A number of observers confirm these conclusions of von Ziemssen.

From a clinical standpoint some recent observations are of great interest. At a meeting of the Leeds and West Riding Medico-Chirurgical Society, January 10, 1890, Dr. Barrs read a paper on an investigation of 74 cases of pleuritis under treatment from 1880–1884 inclusive, and which had apparently recovered from pleuritis, but showing at the present time a death-rate of 57 per cent. Excluding the empyema of children, he thinks the majority of cases of pleuritic effusion are of tubercular origin. Such a series of cases lends strength to the theory of the tubercular origin of pleuritis.

Coriveaud, on the other hand, reports a series of twenty-seven cases followed for from twenty-five years to eight years, and found that none of them became tubercular after attacks of sero-fibrinous pleuritis. Such a series certainly confirms the view, held by probably the vast majority of observers, of the primary and non-tubercular origin of many cases of pleurisy with effusion.

In a paper read before the American Climatological Association, Dr. Vincent Y. Bowditch gives results of an investigation of the subsequent histories of ninety cases of pleuritis occurring in his father's practice, in thirty years, and the conclusions he arrives at, are: that a large percentage of the patients who were afflicted with pleuritis, often in apparently chronic forms, recovered their health, and have not had a recurrence of the trouble, nor developed subsequent pulmonary or other tubercular trouble.

In the last twelve years, of eleven cases of pleuritis with effusion seen in private practice, of which I have records, and the subsequent histories to date, seven were purulent and four sero-fibrinous.

Of the seven purulent, six have apparently recovered, and only one has developed tuberculosis. Five of the seven followed pneumonia. Of the four sero-fibrinous, two have apparently recovered and two developed tuberculosis. It must be admitted, however, that sufficient time has not yet elapsed to give these cases much value. The advocates of the tubercular origin of pleuritis contend that many years may elapse before the pulmonary tuberculosis manifests itself—twenty-four years is the longest period I have found reported. It is very difficult to believe that there is any connection between the pleuritis and the subsequent pulmonary tuberculosis after so long a period, but it is not difficult to find observers who can believe much more improbable associations than this. Baumgarten believes that a child may be born with tubercle bacilli in some of its tissues, and that they may remain inactive for years, or even throughout life. Verneuil goes still farther. He believes that the tubercle bacillus can

exist throughout life in a parasitic form, and then manifest itself in a succeeding generation.

It will be noticed that six of my seven cases of empyema have apparently recovered. I have made no reference to a large number of hospital and dispensary cases observed, as it is impossible to get satisfactory subsequent histories, and the cases would have no value in connection with the subject of this paper. The favorable progress of purulent pleural exudate is in accordance with the experience of von Ziemssen. He reports eighteen cases of empyema. Fifteen of these were treated, of which thirteen recovered. It should be stated that all of these cases of von Ziemssen's followed pneumonia. Many other observers have had a similar experience.

In sixteen cases of dry pleuritis more or less extensive, of which I have kept records, five have thus far developed pulmonary tuberculosis. These were cases occurring in private practice; hospital and dispensary cases are not included for the same reason that such cases were not included in my series of pleurisies with effusions namely, unsatisfactory subsequent histories. Nor were cases included in which at the time there were unmistakable evidences of pulmonary disease. The observations extend over a period of fourteen years and it may be objected that this is not a sufficiently long time to determine the question of a possible development of pulmonary tuberculosis later. Still, up to date, eleven are in such a condition as to justify the opinion that they have recovered.

During the past two years I have had observations made in 140 autopsies in which there were evidences of old or recent changes in the pleura, all cases being included in which such changes were found. These autopsies were performed on subjects from Bellevue and Charity Hospitals, the hospitals of the workhouse and almshouse of the city of New York, and a few were cases of sudden death (coroner's cases) occurring outside of hospitals. There were changes in the pleura, more or less extensive, in nearly 80 per cent. of another series of autopsies, numbering 120, in which this was looked for, not including those cases where only a few fibrous threads connected the surfaces of the pleura. These changes consisted for the most part either in old adhesions, tubercular pleuritis, or recent acute pleuritis secondary to some other disease. These 120 cases were taken at random from autopsies made by Dr. Hermann M. Biggs at different hospitals in New York.

In the 140 cases 47, or 33.5 per cent., died from pulmonary tuberculosis, or else showed quite extensive pulmonary disease; of these, 9 presented unmistakable evidences of tubercular pleuritis. In 50, or a little over 35 per cent. of the remaining cases, cheesy or calcareous nodules were found in the lungs, making in all 97 cases, or 68.5 per cent. in which the lungs showed evidences of recent or old tuberculosis. Taking these two series as a whole, it is found that a little over 60 per cent. of the autopsies showed evidences of old or recent pulmonary tuberculosis, and of these less than one-half died of tuberculosis.

In 27 of the series of 140 cases the pleuritis was recent (in ten of them there were also rather extensive old adhesions), and in 5 instances it was double and associated with pericarditis. In 5 there was anthracosis with fibrous new formations in the lungs, without tuberculosis, but associated with adhesions, as a rule, rather extensive. In 16 other cases there were changes in the pleura, in which the tubercular lesions were found. Of these, 5 were cases of tertiary syphilis, 2 were associated with new growths in the lungs, 5 others showed quite marked renal disease. In one rheumatic case there was acute pleuritis, pericarditis and endocarditis; in one, chronic bronchitis and bronchiectasis; in one, an aneurism of the aortic arch, and one was a case of scleroderma with advanced heart disease.

In speaking of an old process, reference is made to the cheesy or calcareous nodules so frequently found in the lungs, and surrounded by fibrous tissue capsules. Recent investigations have clearly shown that in the vast majority of cases these nodules have resulted from a local tuberculosis; and that the cheesy masses generally, and the calcareous masses frequently, still contain the tubercular virus and will, when inoculated, produce tuberculosis in animals. It should also be distinctly understood, that the nodules found in some of the cases were very small, not more than 3 mm. in diameter, and that in some instances not more than one nodule was found in the lungs. These have been included on the ground that they are exactly the same in nature as the larger masses, and if they are tubercular the question of size does not come into consideration. Fibrous cicatrices without cheesy nodules were not taken into consideration, although many of these unquestionably result from tuberculosis.

As regards the extent and distribution of adhesions, it was found that there was no constant relation between the degree of lung involvement and the extent of the adhesions. In some cases of very advanced disease the pleura showed only a few adhesions. This was especially the case where the process did not involve to any great extent the pleural surface. On the other hand, small nodules in one lung were not infrequently associated with extensive adhesions on both sides, and often the adhesions were more marked in the lung that contained no cheesy nodules.

The observations in these cases do not confirm the assumption that the adhesions are primary, and that they predispose to the development of a

tubercular process in the lungs. The cheesy and calcareous nodules were generally found in the upper lobes, and near the apices, and were not infrequently found in other parts of the lungs also, especially in the upper portion of the lower lobes. When these nodules were found in the lungs, the bronchial glands usually showed similar changes macroscopically.

In the series of 140 cases only 9 showed unmistakable evidences of tubercular pleuritis, although 97 showed evidences of either recent or old tuberculosis in the lungs, and 47 of these showed very extensive involvement.

Post-mortem researches seem to show that tubercular pleuritis is a rare disease, even though the lungs in many cases may be extensively diseased. Undoubtedly many cases of tuberculosis have their first manifestation in a pleuritis, and many cases of pleuritis are secondary to pulmonary tuberculosis. *Possibly* a pleuritis may favor the development of pulmonary tuberculosis by depressing vitality, by lessening the proper lung expansion or by interfering with the nutrition of the adjacent lung; but more probably the same underlying cause produces both.

In the absence of evidences of tuberculosis in other situations there is no sufficiently precise clinical history to warrant an absolute diagnosis of tubercular pleuritis. If it is an effusion, the appearance of the fluid is not characteristic. Unless tubercle bacilli are found one cannot positively affirm its nature, and as has been shown the bacilli are very rarely found.

From my own researches and a study of the researches of others, I offer the following conclusions:

First. If it be true that the very large majority of cases of pleuritis, not traceable to ordinarily recognized causes, are tubercular, we have no clinical method by which the fact can be proven, and the assumption that they are tubercular can only be by inference.

Second. If such a large majority of pleurisies, as many seem to believe, are of tubercular origin, recovery from tuberculosis of the pleura is much more frequent than from pulmonary tuberculosis.

Third. The prognosis in purulent pleural exudate is more favorable as to the subsequent development of tuberculosis than in sero-fibrinous exudate.

Fourth. That even though at an autopsy, evidences of pleuritis recent or old may be found, it does not necessarily follow that the pleuritis is tubercular, because there are tubercular lesions in the lung.

Fifth. It is fair to assume from the frequent association, post-mortem, of recent and old changes in the pleura with pulmonary tuberculosis, that many of these changes are tubercular in origin, although at the time of death tubercles are not found in the pleura.

Sixth. In cases of pleuritis, although evidences of tuberculosis exist in the lungs, as shown by physical signs, and by the presence of tubercle bacilli in the sputa, it does not necessarily follow that such cases of pleuritis are tubercular in origin, although they probably are.

Seventh. In cases in which pulmonary tuberculosis develops subsequent to a pleuritis, there is probably the same underlying cause for each.[1]

ACUTE PERITONITIS FROM GONORRHŒA.

By CHARLES B. PENROSE, M.D., Ph.D.,
Surgeon to Gynecean Hospital and to Out-Patient Department of Pennsylvania Hospital, Philadelphia.

Peritonitis in women is generally the result of disease of the Fallopian tubes. The sequence of events is, in most cases, slow—salpingitis, closure of the fimbrinated end of the tube by peritoneal adhesions, and distention of the tube with pus or other material more or less septic. The resulting peritonitis, if acute and general, is caused by sudden rupture and escape of the tube-contents into the peritoneum; or, if chronic, by gradual leakage from a small rupture, or by direct extension of inflammation through the tubal or abscess wall.

In this way gonorrhœa in women often produces peritonitis and death. But the causative attack of gonorrhœa generally occurs several months or years before the final fatal peritonitis, the peritonitis being a remote sequel of the gonorrhœa, and the infecting virus being of a mixed character. The case which I am about to describe followed a very much more unusual course. The inflammatory process travelled directly from the vagina, through the previously healthy uterus, and along the Fallopian tubes, and thence throughout the general visceral and parietal peritoneum. The action was too rapid to permit the formation of preservative adhesions and occlusion of the fimbriated ends of the tubes.

Similar rapid peritonitis from a septic focus in the vagina or uterus occurs in the puerperal state, after criminal abortion, and after surgical traumatism to the uterus, as in cases reported by Coe (*N. Y. Med. Journ.*, May 15, 1886), when death followed the operation of hystero-trachelorrhaphy, and the autopsy showed septic inflammation, traceable directly from the wounded cervix, along the endometrium and tubes, and thence throughout the general peritoneum. It is, however, probable that in many cases of so-called puerperal peritonitis the rupture during labor of a previously diseased tube, or pelvic tumor of any kind, is the cause of the peritonitis, rather than septic infection from the uterus

[1] I desire to acknowledge my indebtedness for much valuable assistance in the preparation of this paper to Dr. Hermann M. Biggs, one of the Curators of Bellevue Hospital and a director of the Carnegie Laboratory.

or vagina. And it is also very probable that the same cause which was active in the case here reported—that is, gonorrhœa acquired immediately after labor—may be present, though unrecognized, in other cases of peritonitis following childbirth:

In October, 1889, a young colored man came to the Surgical Clinic of the Pennsylvania Hospital with a violent inflammatory attack of gonorrhœa, of several days' duration. He had great dysuria, a very profuse purulent discharge, inflammatory swelling of the whole penis, and œdema of the prepuce. He stated that this was his first attack of gonorrhœa, and that he had acquired the disease by being unfaithful to his wife during her convalescence from childbirth. Seven days after his first visit he had a violent attack of epididymitis on the left side, which obliged him to take to bed.

On October 29th he came at night to my office, walking with crutches, and suffering intense pain. He asked me to see his wife, who was very sick. On visiting the house I found a large colored woman, over 200 pounds in weight, presenting all the symptoms of general peritonitis. The pulse was 130. Temperature 100°. The abdomen was distended and very tender. There was a profuse purulent vaginal and urethral discharge, and redness and inflammatory swelling of the external genitals. Vaginal examination caused great pain, and revealed nothing more definite than fulness on each side of, and posterior to, the uterus. She had free diarrhœa, which had appeared a few hours after the onset of general abdominal pain, and which had greatly relieved the pain.

She and her husband gave me separately the following history. She had always been perfectly healthy, and had had two children, the last on September 24, 1889, one month before the present sickness. The child was healthy in every respect, and the mother convalesced without trouble of any kind, leaving bed on the eleventh day. She had connection with her husband, for the first time after delivery, on October 23d. This was six days before my visit to her, and, as I have said, at this time I was treating the husband for a violent attack of gonorrhœa. Coitus was followed in two days by burning micturition, swelling and inflammation of the vulva, and profuse purulent discharge. Three days later she began to have pelvic pain, greatest on the right side, and free bleeding from the vagina. This was speedily followed by general abdominal pain, tenderness, and distention. Diarrhœa appeared shortly after the general abdominal pain. The bleeding from the vagina lasted four days. As her surroundings were of the worst kind, I sent her to the Gynecean Hospital, and performed abdominal section the next day.

The parietal peritoneum was hypertrophied, being about one-eighth inch in thickness. It did not present the usual smooth surface, but was red and granular, and bled easily. The intestinal loops were adherent to the parietes and to each other in the region of the incision, throughout the pelvis, and in the right iliac and hypogastric regions. All the loops of intestine which were visible were distended, and presented the same red, granular appearance, and bled very easily, even on contact with soft sponges.

There was no lymph, pus, or fluid of any kind in the peritoneum. There were no organized adhesions, all adhesions being very recent and easily separated. The Fallopian tubes were six inches long, and as thick as the index-finger. They were bound by recent adhesions to the surrounding intestines. There was no sign of old tubal disease. The walls of the tubes were thickened, hard, and rigid. The distal ends were not closed. The fimbriæ stood out turgid and stiff. The whole organ was hypertrophied and rigid from recent inflammatory exudation throughout all the structures. A very small quantity of thin, puriform fluid was in the tubes. The tubes and ovaries were removed close to the cornua. The abdomen was freely flushed with hot distilled water, and a large glass drain was introduced. A small quantity of sanguinolent serum was discharged from the drainage-tube, which was removed on the third day.

The convalescence was uneventful. She continued to suffer from urethritis and vaginitis for five weeks after the operation, but is at present well in every respect.

The unusual course followed by the gonorrhœal disease in this case was due to two causes: The virulence of the infecting pus, which was shown by the intensity of the inflammation in the husband, and the patulous condition of the uterus and tubes incident to parturition. Both causes prevented the chronic course of the disease—the gradual formation of peritoneal adhesions and occlusion of the tubes. This would have happened if the patient had survived without operation. The operation accomplished the same result by shutting off the uterus from above, rendering the peritoneum a closed sac, safe from further infection.

I subjoin the report of the microscopic examination of the Fallopian tubes, which was made by Dr. L. Coplin, of the Jefferson Medical College Laboratory of Pathology:

"The tubes show well-marked inflammation, masked by thickening and young cell-deposit through their entire structure. Cocci are present in both tubes, the right more than the left, and in this the processes of inflammation are most developed. The cocci are not gonococci; as they are not diplococci, are not all of them within the perinuclear protoplasm, and do not stain by gonococci stain. They are larger, and are found both inter- and intra-cellular. They are rarely found singly, but as zoogloeic masses, the size of which vary from $\frac{1}{2500}$ to $\frac{1}{1500}$ of an inch, and in these masses may be counted from 25 to 75 or more cocci. They have very much the appearance of some of the staphylococci of suppuration. None of them are streptococci. They are not in the epithelium of the tube, but in the younger connective tissue corpuscles of the margin of the tube. The epithelium is for the most part normal."

University of Halle.—After many erroneous announcements regarding the successor of Volkmann at Halle, the fact is that Professor Bramann is there and has begun his clinics.

CLINICAL MEMORANDA.

MEDICAL.

Case of Slow Pulse.[1]—This patient has continued in much the same condition during the past year. In November, 1889, he had a relapse of which the following is the record:

Nov. 24, 1889. Pulse 11. Frequent attacks of unconsciousness. During the attacks his pulse ceases to beat for ten, fifteen, and twenty seconds.

25th. Pulse 36. Quinine and iron prescribed.

Dec. 1. Pulse 32. Twenty attacks daily.

7th. Pulse 12. Pulse irregular for three or four beats, and then a long interval. Fainting attacks are very frequent.

13th. Pulse 34. Ammonium bromide and belladonna given.

21st. Pulse 12. Fifteen to twenty spells per day.

24th. Pulse 36. Spells not so frequent.

31st. Pulse 13. Very severe attack of syncope.

Jan. 14, 1890. Pulse 26. Very severe attack of syncope.

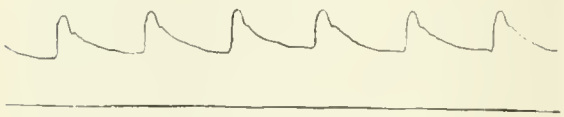
15th. Pulse 18. For a time thought to be dead.

17th. Pulse 18. Better. Temperature 99.6°.

Feb. 6. Pulse 23.

8th. Pulse 13. Slight attacks.

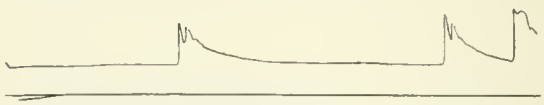
Tracing 1.



Pulse beating 36 per minute.

Tracing 2.

Tracing 3.



Tracing 4.

Tracings 2, 3 and 4 taken when pulse was beating 12 per minute. They show the long diastole—5 seconds.

(Tracings were taken by Dr R. T. Edes.)

9th. Pulse 48. At 8.20 A. M., fell on floor unconscious; black in face; no motion for one hour; choking sound in throat. At 9.15 A. M. constant rolling of the head, then jerking, kicking, and bellowing constantly as though in greatest distress. Takes no notice of surroundings, but put out tongue when told to sharply. Nitrite of amyl and hypodermic injection of morphine and atropine.

10th. Pulse 32. Recovered from attack of yesterday.

15th. Pulse 24.

21st. Pulse 28. Better and sitting up.

27th. Pulse 28. Swelling of face.

April 8. Pulse 28.

On May 14th, when the patient was brought before the Association, his pulse was 24. He was apparently comfortable and was able to be about, though he still had occasional attacks of syncope.

D. W. Prentiss, M.D.

Washington, D. C.

[1] Patient was brought before the meeting of the Association of American Physicians, May 14, 1890. The patient was also shown to the Association in 1889. For more full account of the case see Proceedings of The Association of American Physicians for 1889.

MEDICO-LEGAL.

Collapse of the Lung from Hanging.—Collapse of the lungs in hanging is of such rare occurrence that this case may be of some importance in legal medicine. This condition of the lungs is mentioned once in Taylor's *Medical Jurisprudence;* and I am informed by Dr. John J. Reese, Professor of Medical Jurisprudence in the University of Pennsylvania, that this is the only case recorded.

The case is as follows: B. E., colored, aged twenty-two years, was hung in this city, April 18, 1890, and was given a fall of six feet. Heart-action ceased in twelve minutes after the drop fell. Post-mortem examination held one hour afterward. Temperature in axilla at this time was 98⅘°. Body well nourished, but not very muscular.

Opening the chest, the lungs were found completely collapsed, otherwise normal.

The pleural cavities were entirely free from fluid and were without pleuritic adhesions. The right heart was distended with dark blood. The stomach contained a small amount of blood but no food, and there was marked capillary engorgement. Bowels were empty. The vessels of the liver and kidneys were engorged. Spleen normal.

Bloodvessels of brain distended.

Careful dissection of the neck showed that the articulations of the vertebræ were intact.

Cunningham Wilson, M.D.

Birmingham, Alabama.

MEDICAL PROGRESS.

Experimental Studies in Tuberculosis.—At the Heidelberg congress of German naturalists and physicians Schottelius stated that some years ago he instituted a series of experiments with tuberculous lungs interred in a wooden box at a depth of five feet, the usual mode of sepulture of bodies. After two years and a half he removed from the surrounding earth a quantity of tubercle bacilli, for the most part spore-producing. From these he obtained pure cultures which furnished positive results in 80 per cent. of his experiments in inoculation. He is now engaged in investigations with the object of ascertaining whether the virulence resides in the bacilli taken from the soil or in their spores. Soyka expresses the opinion that the greater number of the bacilli perish, but that

some possess durability and may recover their virulence under favorable conditions. Gärtner has observed bacilli in a cemetery abandoned for twenty-five years.

As a practical outcome of his investigations, Schottelius advises the disinfection of bodies of persons dead from infectious diseases.

Gebhardt has experimented with the sputum of consumptives, his object being to test the virulence of the sputum in different grades of dilution, and to ascertain whether the potentiality of the tubercular virus is essentially modified by the organ first infected—that is to say, by the manner of infection. With this object he practised hypodermic and intraperitoneal inoculation and experiments in inhalation and alimentation, and ascertained that in the subcutaneous connective tissue, the peritoneum, and the lungs the tuberculous virus multiplies in about an equal degree, while the digestive apparatus offers resistance. Hence tubercular virus may, especially in small quantities, pass through certain organs without provoking local alterations. As the point of ingress is not always the seat of the disease, pulmonary tuberculosis is not to be invariably attributed to infection by inhalation.

Sputum which contains bacilli is exceedingly infectious, retaining its virulence even in dilution of 1 : 100,000, apparently without regard to the manner of infection. The virulence of the sputum being in proportion to the quantity of bacilli present, Gebhardt employed pure cultures of the bacilli of tuberculosis, on the hypothesis that equal quantities of the same culture contain quantities of bacilli. With a subcutaneous inoculation of 1 c. c. of a dilution in the proportion of 1 : 400,000 and an inhalation of 0.5 c. c. of the same dilution in a culture of agar-agar he obtained positive results. Hence the pure cultures retain their virulence when enormously diluted.

Malassez and Vignal desiccated the sputum of tuberculosis, moistened it with water, again desiccated and pulverized it, and this repeatedly, endeavoring to realize, as far as possible, the conditions to which the sputum daily ejected in our streets is subjected. After successive desiccation and moistening the bacillus of the sputum retained all its virulence.

With regard to the penetration of tubercle bacilli into the organism, Dobroklonski states, as the result of his experiments in the Cornil laboratory at Paris, that tuberculosis may attack the organism by way of the digestive apparatus. For this to occur, no lesion of the intestinal wall, epithelial desquamation, local modification, nor previous inflammation is necessary. The tuberculous virus (bacilli and spores) may easily traverse the completely normal epithelial lining of the intestine, but it does not determine inflammation unless it remains for a length of time in contact with the intestinal wall. Dobroklonski asserts that the spores and bacilli do not penetrate the organism by any fixed means, but that they are carried by the current of the lymphatic system, and, being arrested by the tissues, determine in them the formation of tubercles.

As a natural inference from Hirschberger's experiments demonstrating that tuberculous cows, or cows infected with tubercular phthisis, produce, in 55 per cent. of cases, infectious milk, it was supposed that milk from large dairies would contract virulent properties from the infectious milk of one tuberculous cow. A series of experiments, conducted by Gebhardt, under the direction of Bollinger, in the Pathological Institute of Monaca, show that tuberculous milk loses its virulence at a certain dilution. The mixing of milk practised in large dairies diminishes the danger, and in most cases renders the milk innocuous. Milk served by large dairies is always to be preferred to the continued use of milk from one cow.

Studies in the transmission of tuberculosis from animals to men by means of tuberculous milk, directed the attention of hygienists to the derivatives of milk, the most important of these being butter. Gasparini inoculated guinea-pigs with butter containing the bacillus of Koch, and by microscopic observation verified tubercular lesions in almost all cases.

Referring to his studies of the infectious property in the flesh of tuberculous animals, Kastner stated that the object of his experiments was to ascertain if such flesh contained virus, and to what extent the consumption of such flesh as meat was dangerous to man. From the results of his experiments he concludes that the danger is slight, unless the nodules of tuberculosis are formed in the meat, which is rarely the case.—*Weekly Abstract of Sanitary Reports, U. S. Marine Hospital Service*, June 13, 1890.

Effects of Caffeine.—In an able article on the study of caffeine DR. EDWARD T. REICHERT reached the following conclusions:

1. The pulse-rate may be diminished during the first and last stages of the poisoning, but is generally decidedly increased. During the first stage the diminution is due to stimulation of the cardio-inhibitory centres in the medulla oblongata and heart, and during the last stage to a direct depression of the heart. The increase in the pulse-rate is due to a depression or paralysis of the above-mentioned cardio-inhibitory centres.

2. Arterial pressure during the first stages of poisoning is generally either unaffected or diminished, but occasionally a trifling increase is noted; during subsequent stages it is diminished. The increase is due to a direct stimulant action upon the bloodvessel walls increasing vascular tension. The diminution is due chiefly to a direct depression of the heart, and to some extent, doubtless, to a secondary paralysant action on the vessel walls.

3. The acceleration of the heart-beats may be accompanied by no appreciable alteration in blood-pressure, but generally by a more or less decided diminution, which is dependent upon cardiac depression.

4. Caffeine diminishes the heart's efficiency for work, arrests it in diastole, sometimes induces sudden paralysis, and is, therefore, a cardiac depressant.

5. The asserted stimulant action upon the circulation is, doubtless, subjective, and dependent upon an excitation of the cerebral centres.

The Effect of Opiates on Gastric Secretion.—According to the *Lancet*, DR. ABUTKOFF has examined the effects of opium and two of its alkaloids on the digestive functions of healthy people. He found that the three substances experimented with—viz., opium, morphine, and codeine—all exert a retarding action on gastric digestion by diminishing the general acidity of the gastric juice. Neither the quantity of pepsin nor the absorbent power of the

stomach appeared to be affected by any of the three substances. As to their relative effects in such doses as can be given medicinally, opium had decidedly the most marked influence, and codeine the least. Dr. Abutkoff suggests that in the case of patients with weak digestion, due to deficiency of acid in the gastric juice, opiates should be given some hours after a meal, but that where the hydrochloric acid is excessive, they may be given with meals.

Surgical Treatment of Tubercular Peritonitis.—CZERNY, of Heidelberg, has recently published his views upon surgical interference in cases of tubercular peritonitis. It is pointed out that though the records of operations seem to show that the disease is amenable to such treatment, it should be remembered that tubercular inflammation of a serous membrane usually indicates that tuberculosis has reached an advanced stage and has become diffused. Czerny grants that surgical treatment of tubercular lesions may, under certain circumstances, bring about an improvement in the nutritive processes, and thus aid in eliminating the virus, and, in cases of restricted localization, lead to a definite cure. It is different, however, when there are many infecting foci.

It is held that the prospects offered by surgical interference will depend upon a distinction being made between the variety of this affection characterized by the presence of a fluid exudate with miliary tubercles, and the dry form in which large tubercular nodules are found; operation in the latter variety being very unpromising. In the former variety the author regards incision and removal of the fluid much preferable to any other plan of treatment, but he also holds that the ultimate results of such treatment are not very encouraging.—*London Medical Recorder*, March 20, 1890.

Intubation of the Larynx.—DR. G. HUNTER MACKENZIE describes the following cases illustrative of the complications which may arise during intubation of the larynx (*British Medical Journal*, May 24, 1890).

CASE I.—A child of twenty-one months intubated for membranous croup (laryngeal diphtheria?). The insertion of the tube was immediately followed by great relief, and all went well until six hours later, when profuse bleeding from the mouth and nose began, and the child very quickly died. Post-mortem examination showed a blood-clot firmly plugging the tube, and an erosion of the inferior laryngeal artery and vein. The erosion was evidently not caused by the tube.

CASE II.—A child of three and a half years suffering from "croup" (no mention of false membrane is made). The immediate results of the operation were excellent, the child breathing easily for seventy-two hours. At the end of this time he suddenly died, and on removal the tube was found blocked by a firm dry purulent mass.

CASE III.—In this case the insertion of the tube was difficult and, as Dr. Mackenzie doubted that the tube was in the larynx he did not remove the silk cord, but fixed it externally by means of adhesive plaster. A few hours before death the child gnawed through the cord, and at the *post-mortem* the tube was found in the lower part of the œsophagus. The difficulty in introduction was due to supra-glottic narrowing and distortion of the larynx.

Dr. Mackenzie has in a few instances seen the tube expelled by coughing, but writes that this need not cause alarm as there is usually sufficient time for reinsertion.

Since his experience with the second case above reported he has made it a rule to remove and examine the tube within forty-eight hours after its insertion. If dyspnœa then returns, which is the exception, the tube is replaced. The difficulty in swallowing is another reason why the tube should not be left in position longer than absolutely necessary.

Dr. William Hales in the same number of the *British Medical Journal* reports one hundred cases of intubation with 38 per cent. of recoveries and with seven consecutive successful cases.

Nitrite of Amyl in After-pains.—WINTERBURN employs nitrite of amyl for the relief of severe after-pains. His method of using it is as follows: A small piece of tissue-paper is saturated with five or six drops of the nitrite, then placed in a two-drachm vial, which is tightly corked.

The patient is directed to take out the cork and inhale from the bottle when the pains are severe.—*Archives of Gynecology*, June, 1890.

Powder for Fœtid Perspiration.—

R.—Powdered rice . . .	2	ounces.
Bismuth subnitrate . .	7	drachms.
Potassium permanganate	3	"
Powdered talc . . .	1½	" —M.

To be dusted upon the perspiring parts.—*College and Clinical Record.*

Prescription for Removal of Comedones.—MCCASKEY uses the following application in the treatment of comedones:

R.—Sulphuric ether . . .	8 drachms.
Ammonium carbonate .	1 drachm.
Boric acid . . .	20 grains.
Water, sufficient to make	2 ounces.—M.

To be applied locally twice daily.—*Peoria Medical Monthly.*

Ferruginous Tonic Pills.—The following formula is quoted in the *Archives of Gynecology*:

R.—Powdered digitalis Ext. of nux vomica Carbonate of iron	of each	8 grains.
Sulphate of quinine . .	1	drachm.
Ext. of gentian, sufficient quantity.		

Mix and divide in thirty pills, of which one should be taken three times daily.

Prescription for Cases of Pin-worms.—The *Pittsburgh Medical Review* quotes the following formula, to be used in cases of pin-worms:

R.—Tincture of rhubarb . .	30	minims.
Magnesium carbonate .	3	grains.
Tincture of ginger . .	1	minim.
Water	1½	drachm.—M.

Three or four such doses should be given in twenty-four hours.

GONORRHŒA IN WOMEN.

THE serious complications which may result from gonorrhœa in women have only been fully recognized within very recent years. Noeggerath's statement that over one-half of the women of New York have some disease the result of gonorrhœa, seemed very much exaggerated when it was first made; but the results of abdominal surgery have strengthened this opinion.

Gonorrhœa in women is not only a cause of salpingitis, and resulting sterility and invalidism, but it is not infrequently the cause of death. The mortality of untreated cases of pyosalpinx is difficult to determine; we have seen it variously estimated at from ten to twenty-five per cent. In a consecutive series of fifty cases of pyosalpinx which were operated upon, we have found general peritonitis present in six cases. These six women were in a dying condition, and they alone, if not subjected to operation, would have given a mortality of twelve per cent. for this series of cases—a mortality certainly much too small when we consider the dangers to which the remaining forty-four women were constantly exposed. It is often difficult to estimate the part played by gonorrhœa in the production of salpingitis. The great majority of women who have pyosalpinx have been exposed to gonorrhœal contagion; but they have also been exposed to other causes of pyosalpinx, a very frequent one of which is criminal abortion. The presence of the gonococcus in the Fallopian tube is pathognomonic; but we believe that there are many cases of salpingitis caused primarily by gonorrhœa, in which careful search fails to reveal the specific diplococcus. This opinion is based on the examination of many specimens of tubal disease, with an undoubted clinical history of gonorrhœa, in which no gonococci were discoverable.

A case recently reported by DR. E. CAPPI (*Gaz. Hebd. des Sciences Méd. de Montpellier*, May 24, 1890) is of interest in this connection. A woman was operated upon for encysted peritonitis, and the gonococcus was found not only in the pus from the abdomen, but also in the discharge from the os uteri. Though the operation failed to show the primary cause of the abdominal abscess, yet it most probably originated from the rupture of a pyosalpinx of gonorrhœal origin. This case followed the usual course; the sequence of events being: vaginitis, endometritis, salpingitis, and closure of the Fallopian tubes; and finally, encysted peritonitis with the formation of a pelvic or an abdominal abscess, or general diffuse peritonitis following rupture of the tubal abscess. The case of peritonitis from gonorrhœa reported by DR. PENROSE in this number of THE MEDICAL NEWS followed a very unusual course. The progress of the disease was not delayed by local peritoneal adhesions resulting in closure of the Fallopian tubes. We know of no case with a similar history; and though the gonococcus was not discovered, yet the clinical history points so definitely to the cause that we must conclude that the disease was of gonorrhœal origin.

This case exemplifies in a forcible way the dangers of gonorrhœa in women. The physician should always remember that neglected gonorrhœa is dangerous not only on account of the consequences to the male, such as urethral stricture, cystitis, and epididymitis, but also on account of the much more frequent and more serious sequelæ which may occur in the female.

TRICHLORACETIC ACID IN INTRA-NASAL DISEASES.

THOUGH the galvano-cautery has to a great extent supplanted chemical agents in the treatment of hypertrophic rhinitis, in many cases the cicatrix produced by the application of pure chromic acid is sufficient to cause contraction of the turbinated

bodies, and possesses the advantages of not alarming the patient and of requiring comparatively little manipulative skill. Its disadvantages are that unless considerable care is exercised the acid spreads, causes an unnecesarily large slough and an undesirable amount of inflammatory reaction.

Trichloracetic acid, recently introduced in Germany as a cauterant, apparently has all the advantages and none of the disadvantages of chromic acid. Von Stein and Stanislaw, of Moscow (*Journal of Laryngology and Rhinology*, June, 1890), recommend it not only in the treatment of hypertrophy but in that of acute nasal catarrh (coryza), ozæna, adenoid vegetations, and of various laryngeal diseases. Making due allowances for the enthusiasm of the experimentalists, their assertions are are still so positive that the drug should certainly be given a fair trial, although we believe its field will eventually be restricted to the cauterization of hypertrophies and possibly as a stimulant in the treatment of ozæna.

As a cauterant a crystal of the pure acid should be applied by means of a probe, precisely as chromic acid is ordinarily used, and, of course, during cocaine anæsthesia.

In ozæna a weak solution (five-tenths of one per cent.) should be rapidly brushed over the diseased mucous membrane. It is stated that this treatment, if repeated daily, corrects fœtor, softens the crusts and prevents their formation.

CORRESPONDENCE.

"DETACHMENT AND EXPULSION OF THE VAGINAL PORTION OF THE CERVIX DURING LABOR."

To the Editor of The Medical News,

Sir: Under the above title, in the last issue of your journal, Dr. Hirst reports a case which is of considerable interest. The treatment of the case, however, strikes one as somewhat peculiar. Is it considered orthodox practice in Philadelphia to allow a multiparous woman to remain in labor attended by "vigorous uterine contractions," supplemented by "energetic abdominal action," for *twelve* hours, or, in fact, until the "vaginal portion of the cervix" is extruded from the vulva, without extending to her a helping hand? Could not the os uteri have been dilated artificially? And, if other means failed, could not the tissues surrounding the os (even though they had undergone "cicatricial infiltration") have been subjected to multiple incision (*débridement multiple*), and then the delivery have been carefully effected with forceps under chloroform? Dr. Hirst says: "the absence of serious symptoms after an injury of this gravity is remarkable." It is still more remarkable, in view of the practice adopted, that the body of the uterus did not rupture before the cervical portion gave way under the influence of the *vis a tergo*. Dr. Hirst seems to think that the recovery of the patient, without "serious symptoms," speaks well for the *asepsis* of the Maternity Hospital. We think that it speaks well for the *vis medicatrix naturæ*, and are inclined to attribute the recovery of the patient more to good luck than good management.

A Reader of The News.

June 16, 1890.

Before printing this note the Editor of The Medical News submitted it to Dr. Hirst for reply, which is appended:

To the Editor of The Medical News,

Sir: As I did not see the case reported by me in the last number of The News until after the cervix had been detached and expelled, the rather harsh criticism of "A Reader of The News" applies to the conduct of the resident physician in charge. Her action did not appear so heinous to me as to this critic. Would he, in a first stage of labor, which had only lasted twelve hours, uncomplicated by rise of the contraction-ring, by elevation of temperature, by marked disturbance of pulse, by anything, in fact, but delayed dilatation of a rigid cervical canal—would he, I ask, resort to the forced dilatation of the cervix, or to its incision? If so, he would find his "meddlesome midwifery" more dangerous than the conservative course pursued by the young graduate of not a year's standing, who was in charge of the case.

Barton Cooke Hirst, M.D.

PTOMAINES AND BACTERIA.

To the Editor of The Medical News,

Sir: My attention has just been called to a short article on ptomaines by Professor Ernst, of Harvard, in Volume V. of the *Annual of the Universal Medical Sciences*, 1889, and while the entire article might justify some comment, I am certainly at a loss to understand what authority Professor Ernst has for saying that Mr. Novy and myself in our little volume on *Ptomaines and Leucomaines* make "the suggestion that bacteria may be the *products* of these alkaloids." Will Professor Ernst be kind enough to inform me on what page of the volume I will find the suggestion? As the author of that portion of the volume in which a ptomaine is defined and its nature discussed, I had never heard of the "suggestion" until I had the pleasure of reading the article by Professor Ernst. Respectfully,

V. C. Vaughan, M.D.

The above having been submitted to Professor Ernst, he replied as follows:

To the Editor of The Medical News,

Sir: The statement to which I referred and to which Dr. Vaughan wishes to be directed will be found in *Ptomaines and Leucomaines, or the Putrefactive and Physiological Alkaloids*, by Victor C. Vaughan, M.D., and Frederick G. Novy, page 86, sixth line from the bottom, reading "we are justified in saying that the microörganism may be an accompaniment or a consequence of the disease."

My attention was first called to the statement by a review of the book in the *American Journal of the Medical Sciences*, October, 1888, page 394.

Respectfully,
HAROLD C. ERNST, M.D.

TYPHOID FEVER IN CHATTANOOGA.

To the Editor of THE MEDICAL NEWS,

SIR: In an interesting paper by Dr. James E. Reeves, of Chattanooga, Tennessee, on "Some Points in the Natural History of Enteric or Typhoid Fever," read before the Association of American Physicians, in May last, and published in THE MEDICAL NEWS of June 7th, the author claims for Chattanooga a remarkable and almost entire immunity from typhoid fever, and quotes several well-known physicians of that city to prove that typhoid fever is a disease of extremely rare occurrence—one physician, in active practice for more than thirty years, having seen only three or four cases within that period.

The official records of the Chattanooga Board of Health, as favorable as they are, scarcely justify these extraordinary claims. The reports of the board charge 107 deaths to typhoid fever during the last four years. This mortality probably represents over 1000 cases of the disease. At all events, there appears a marked discrepancy between Dr. Reeves's conclusions and the official figures of the Health Department.

I observe, furthermore, that the Board of Health calculates the rate of mortality upon an estimated population of 40,000 instead of 60,000, the estimate adopted by the writer of the paper.

In studying the natural history of any disease as influenced by local conditions and environment, the official figures adopted by competent persons charged with the responsibility of collecting and publishing statistical data are entitled to serious consideration, and should outweigh, it seems to me, the random estimates of individuals, however capable and honest they may be.

The line between facts and mere opinions should be sharply drawn, and the opinions, to be trustworthy, should be supported by the facts; otherwise confusion may ensue, innocent persons may be misled, and evil may come when only good was intended.

Respectfully,
JAMES B. BAIRD, M.D.

ATLANTA, GEORGIA.

IODOFORM AND IODOL IN DIABETES MELLITUS.

To the Editor of THE MEDICAL NEWS,

SIR: I have just read a very interesting inaugural thesis by Dr. Fructuoso V. Valdés, presented last year to the National School of Medicine of Mexico. The subject of Dr. Valdés' essay is "Iodol," and in it he reports the excellent results obtained, by the local use of the drug, in the treatment of ulcers in general. The observations were made in the different hospitals of the Mexican capital, under the supervision of the ablest clinical professors. Among other cases, he reports, through the kindness of Dr. José Olvera, of the City of Mexico, in whose private practice they occurred, two of diabetes mellitus, in one of which the most flattering success followed the use of iodoform, in the other from the use of iodol.

I will translate the details of both cases, as they are extremely interesting, one of them corroborating the results obtained in a case recently reported by me.[1]

Dr. Olvera writes as follows: "Last year I attended a lady about fifty years of age, who was then suffering from glycosuria accompanied with polyuria (about 2½ litres of urine daily), general debility, intense thirst, and a very disagreeable dryness of the mouth and fauces. The first time that the urine was analyzed by Professor Morales it gave 33 grammes of glucose and 30 grammes of urea per thousand of the liquid. The patient, four years previously, had suffered for six months from nephritis with albuminuria. She recovered completely, but afterward had a rheumatic facial paralysis of the right side. It was impossible for me to ascertain, at the time of consultation, the length of time since she began to have the diabetic affection, nor the cause of the disease. She was submitted to a rigorous diet, excluding all sugary and amylaceous food, but was allowed to use bran bread. I prescribed a daily dose of 0.005 milligramme of strychnine, and at the end of the second month the 33 grammes of glucose determined by the first analysis had only been reduced by 2 grammes. I then administered a combination of iodoform and strychnine. The third time the urine was analyzed, the reduction was very noticeable, as the liquid gave only 18 grammes of glucose, which encouraged me to continue the treatment. At the end of three months the sugar had *entirely* disappeared from the urine. I deemed it prudent to continue the same diet and medicines for a month and a half longer, after which she was allowed to use gradually amylaceous and sugary articles of food. Notwithstanding the free ingestion of these in the course of time, no glucose could be detected by later analyses, a fact which greatly strengthens my belief that it was, undoubtedly, a case of perfect cure.

"Mrs. R. L. presenting an emphysematous condition and symptoms of a slow, progressive medullary sclerosis, began to notice last December an increase in the secretion of urine, especially at evening, which was the cause of sleepless nights. At first she attached no importance to this circumstance and attributed the disturbance to cold; but the continuous and gradually increasing dryness of the mouth and fauces decided her to consult me at the end of January last. The urine was analyzed by Professor Morales, who found 29 grammes of sugar per thousand of the liquid. The amount of urine passed in twenty-four hours was calculated to be 1200 grammes. Remembering the good results obtained from the combined use of iodoform and strychnine in the previous case, I immediately proceeded to treat the present one with the same agents. These were administered during one week only and then, according to the suggestion of Dr. Valdés, I decided to substitute the iodoform with *iodol*, but continuing to give strychnine. The analysis of March 3d gave only *three grammes* of glucose per thousand of urine. The total amount of urine passed in the twenty-four hours has also diminished considerably. It is, perhaps, needless for me to say that the patient's diet has been properly regulated.

"From what has been here stated I think we ought to

[1] THE MEDICAL NEWS, vol. lv., March 8, 1890.

congratulate ourselves on the happy results obtained in the latter case. In the first case it may be that, while the diminution of the glucose was slower under the use of iodoform and strychnine than that of the second case under iodol and strychnine, the more rapid disappearance of the sugar was due not to the action of the drugs, but to the constitution of the patient, the nature of the cause or causes of the disease, idiosyncrasies and what not; however, setting these considerations aside, we have sufficient reason to continue our experimentation in this matter, and further experience will, in the future, decide the usefulness or worthlessness of the drug in question."

I can only add that there is, undoubtedly, sufficient clinical evidence to show that iodol deserves further and continuous trials at the hands of the profession, and not simply as a substitute for iodoform but as a drug possessing its own and highly valuable therapeutical properties.

I am about to make an experimental physiological study of iodol, which will form the substance for a future article.

NEWS ITEMS.

A New Hospital at Zanzibar.—The Emperor of Germany has subscribed 20,000 marks to help in the establishment of a new German hospital at the capital of Zanzibar, in East Africa.

University of Berlin.—*The Lancet* announces that the chair of mental pathology at the University of Berlin, made vacant by the death of Professor Westphal, has been accepted by Dr. Grashey, of Munich.

Protection of the Insane against Fire.—In view of the frightful loss of life from the burning of asylums at Montreal, Canada, and Utica, N. Y., the Committee of Charities of the Massachusetts Assembly have framed a bill requiring iron fire-escapes to be constructed on the outside of all asylums for the insane throughout the State. Suitable apparatus for the distribution of water-hose within the buildings will be required, and the trustees are directed to cause a regular monthly inspection to be made of these life-saving appliances.

The Death-rate of England.—The death-rate in England in 1889 was 17.9 per 1000; in 1888, 17.8 per 1000. For each of the nine years, 1881–1889, the rate was lower than in any year prior to 1881, and the average annual rate for that period was only 18.9 per 1000. For the ten years, 1871–1880, the average annual rate was 21.4 per 1000. This shows a saving of 2.5 in every 1000 of the population, comparing the last two decades with each other. The Registrar General of England estimates that not less than 600,000 people in England and Wales at present survive by reason of the declining mortality rate—that is, if the rate 21.4 per 1000 had persisted in the past nine years instead of falling to 18.9, there would have been 600,000 more deaths.

This improvement is no doubt largely referable to the improved sanitary condition of the United Kingdom, more especially in the great cities. One proof of this is seen in the decreasing mortality from zymotic diseases, such as smallpox, scarlet fever, and typhoid fever. Infant mortality, also, has shown a marked decline, and is another index of the life-saving results of an improved sanitation.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 24 TO JUNE 30, 1890.

By direction of the Secretary of War, leave of absence for two months, to take effect August 6, 1890, is granted to William N. Suter, *First Lieutenant and Assistant Surgeon.*—Par. 3, *S. O. 140, A. G. O.*, June 26, 1890.

By direction of the Secretary of War, leave of absence for three months and fifteen days, to take effect as soon as his services can be spared, is granted William C. Borden, *Captain and Assistant Surgeon*—Par. 11, *S. O. 46, A. G.O.*, June 23, 1890.

Captain Howard Culbertson (Retired) died June 18, 1890, at Zanesville, Ohio.

Appointments in the Medical Department, U. S. Army, to be Assistant Surgeons, with the rank of First Lieutenant, June 6, 1890:

Keefer, Frank R., of Pennsylvania, vice Woodruff, promoted.

Raymond, Thomas U., of Indiana, vice Newton, resigned.

Snyder, Henry D., of Pennsylvania, vice Wilson, resigned.

Smith, Allen M., of New York, vice Matthews, promoted.

Heyl, Ashton B., of Pennsylvania, vice Hall, promoted.

Clarke, Joseph T., of New York, vice Porter, resigned.

By direction of the Secretary of War, Charles R. Greenleaf, *Major and Surgeon*, will attend the encampment of the Pennsylvania National Guard at Mount Gretna, Pennsylvania, from the 18th to the 26th of July, 1890, for the purpose of accompanying the Surgeon General of Pennsylvania in his inspection of the camp.—Par. 11, *S. O. 144, A. G. O.*, June 20, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING JUNE 28, 1890.

Page, John E., of Berryville, Va.—Commissioned Assistant Surgeon in the Navy.

Kennedy, Robert M., of Pottsville, Pa.—Commissioned Assistant Surgeon in the Navy.

Whitfield, James M., of Richmond, Va.—Commissioned Assistant Surgeon in the Navy.

Stone, Lewis H., of Litchfield, Conn.—Commissioned Assistant Surgeon in the Navy.

Atlee, Louis W., *Assistant Surgeon.*—Detached from the U. S. S. "Marion, and granted three months' leave.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM MAY 31 TO JUNE 21, 1890.

Gassaway, J. M., *Surgeon.*—When relieved at Cairo, Ill., to proceed to New Orleans, La., and assume command of the Service at that station, June 4, 1890.

Stoner, G. W., *Surgeon.*—Granted leave of absence for three days, June 18, 1890.

Wasdin, Eugene, *Passed Assistant Surgeon.*—Granted leave of absence for fourteen days, June 5 and 10, 1890.

White, J. H., *Passed Assistant Surgeon.*—To proceed to Savannah, Ga., on special duty, June 9, 1890.

Heath, F. C., *Assistant Surgeon.*—Granted leave of absence for fifty-eight days, June 10, 1890.

Magruder, G. M., *Assistant Surgeon.*—Granted leave of absence for twenty days, June 2, 1890. Ordered to examination for promotion, June 5, 1890.

Woodward, R. M., *Assistant Surgeon*—Relieved from duty at Chicago, Ill., to assume command of Service at Cairo, Ill., June 4, 1890

Condict, A. W., *Assistant Surgeon.*—Upon expiration of leave of absence, to report to Medical Officer in command at Chicago, Ill., for duty, June 4, 1890.

Resignation.

Heath, F. C., *Assistant Surgeon.*—Resignation, to take effect August 31, 1890, accepted by the President, June 10, 1890.

THE PATHOLOGY AND TREATMENT OF CLUB-FOOT, ESPECIALLY VARUS AND EQUINO-VARUS.

With Brief Reports of Fifteen Excisions of the Astragalus for Correction of the Deformity.[1]

BY THOMAS G. MORTON, M.D.,
SURGEON TO THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

CLUB-FOOT is not a product of modern civilization; it existed as far back as our records extend; and it presented the same problems to the early physicians that it does to the surgeon of to-day. It is only our ideas as to its pathology and methods of treatment which have been changed. If, at the present time, we can make a more correct diagnosis and have more successful results, we can justly ascribe our advances to the genius and practical skill of Stromeyer, and preëminently to Lister, under whose teachings operations have become possible the results of which may be justly claimed as among the triumphs of modern surgery.

If we consider the history of the operative treatment of club-foot, we find that it naturally divides into three periods, or stages of development. In ancient medicine such poor results followed cutting operations that they were practically abandoned. During this first period little advance was made, and for over two thousand years the teachings of Hippocrates upon the subject had full sway in the medical world. All operative interference was condemned, and the treatment of the deformity consisted in the use of manipulation and bandages, or fixed apparatus, and hygienic measures. With the simpler forms of club-foot this sufficed, as it still does in many cases to-day; but during this period the graver forms of deformity were regarded as hopeless malformations beyond relief, and were the opprobrium of surgery. Even so recently as 1839, we find Dr. Little stating in the preface to his classical treatise on Club-foot, that "until within three years such cases had been to a considerable extent confined to the care of the instrument-maker."

The second period began about 1834, when Stromeyer published an account of his new method of tenotomy, and directed attention anew to the treatment of club-foot. Although it was left for Stromeyer to make this operation a practicable one by subcutaneous tenotomy, division of the tendo-Achillis had been previously successfully performed by Lorenz, in 1784, and by Petit, of England, in 1779. It had also been successfully performed in 1816, by Delpech, to whom the credit is due of having first indicated the principle, which he was unable to carry out, of keeping the wound secure from contact with the air, in order to obtain satisfactory results.

The third and present period began with the introduction of antiseptic wound treatment, first scientifically formulated by Sir Joseph Lister, less than a score of years ago.

With thorough antisepsis the dangers of inflammation and suppuration may be said to exist no longer. The operator may now safely explore the ankle-joint, divide tendons or fascia by open incision; remove a wedge from the tarsus; extirpate the astragalus, cuboid, or any other portion of the joint; in short, do whatever may be deemed necessary to secure proper redressment of the foot, without fear of the consequences, or causing more reaction, as the rule, than that from a simple incision.

Pathology and Morbid Anatomy.—The pathology of congenital club-foot, in some points, is perhaps still unsettled. In the acquired non-traumatic form it is generally admitted that the majority of cases have their origin in infantile paralysis, although other influences and lesions may likewise cause the deformity.

Regarding the intimate nature or the cause of congenital club-foot, there are good reasons for believing that in most cases, if not in all, the affection in its pathology resembles very closely the infantile form of spinal paralysis, if, indeed, it be not identical with it. In any given case of congenital club-foot, however, we will find in one or more of the muscles or groups of muscles of the leg and foot more or less paresis or actual paralysis, and in other opposing or correlated muscles tonic spasm, or contraction. In consequence of the nerve lesion, the supply of nerve force to the limb is defective, disturbances of nutrition naturally follow, and more or less atrophy results, which even under the most favorable circumstances is never more than partially recovered from.

This may be easily understood when we recall the fact that not only is the growth of muscle and bone impaired, but as Cruveilhier pointed out, even the

[1] Read before the American Surgical Association, May, 1890.

nerves and bloodvessels are imperfectly developed, and are smaller than in the normal limb. Where there is double club-foot, we can say positively that there never will be even fairly well-formed extremities; the legs are much more spindle shaped than in the single form, because the central lesion has been more severe. That cell-life and cell-growth are seriously affected by the original lesion is manifested by the general atrophy, involving all the structures of the foot, leg, and thigh; the circulation is defective, as is demonstrated by the blueness of the skin and the comparative coldness of the extremity. The leg and thigh bones are shorter and of smaller size than on the sound side, and this want of symmetry of the limbs becomes more and more evident as the patient advances to adult age.

It seems only reasonable to assume in explanation of the difference between the various grades of congenital club-foot, that the amount of deformity is dependent upon the extent of the lesion, and also upon the period of intra-uterine life during which the nerve lesion or palsy occurred. If the palsy occurred at an early stage of fœtal development, it is likely to give rise to the more marked forms of tarsal distortion, because the tarsus when cartilaginous is more readily affected by the force exerted by abnormal muscular action. On the contrary, should the paralysis occur toward the close of gestation, the tarsus being already formed, there is less likelihood of malformation or displacement of the bones, and the distortion is mainly in the soft structures.

It is perhaps not possible to determine positively when the intra-uterine paralysis occurs, which results in the formation of any case of club-foot. In some cases we find one or more of the tarsal bones involved in the deformity, in others only the soft structures; and when the bones are displaced and misshapen it seems probable that there must have been long-continued paralysis of some muscles and contraction or spasm of others. If the palsy occurred very early in fœtal life an entire change in the bony joint may result, the principal variation in such a case being likely to involve the position of the astragalus. When the palsy has occurred at a later period of intra-uterine life, the anterior tarsus may become somewhat displaced, and later on, when the os calcis and the astragalus are fairly well ossified (or subsequent to the seventh month), the distortion will probably be found almost entirely in the soft parts. Later on in life we find severe, aggravated, or so-called inveterate forms of varus, or equino-varus, due either to ineffectual or improper treatment, to neglect after operation, or to the entire want of treatment.

The most important features in the pathology of club-foot, therefore, may be said practically to consist in:

1. The period of life at which it occurs.
2. Whether the foot has been used in walking.
3. Whether there has been any previous treatment or unsuccessful operations.

A consideration of these points will naturally indicate the general outline of treatment.

Varieties of Club-foot.—In every case of club-foot we find interference with the function of the ankle and foot, with limitation of the normal range of mobility, usually accompanied with more or less deformity or distortion. When this limitation exists in the antero-posterior plane we have either inversion or eversion of the sole of the foot (talipes varus or valgus); or we may have combinations of both forms (talipes equino-varus or valgus, talipes calcaneo-varus or valgus).

At birth there is one form of club-foot which is of such constant occurrence that it may be regarded as the typical congenital variety; it is varus or equino-varus. In comparison with this all other forms of club-foot are very infrequent.

Treatment.—The more modern treatment of talipes, by the aid of which we are enabled to accomplish so much for its relief, is the direct result of our present methods of wound treatment. I repeat, that it would not have been possible to perform the operations now practised, nor to have improved so generally upon the old methods of treating these deformities, without the aid of antiseptics. We can now, without danger, and in a very short time, accomplish more than could ever have been gained by the former measures, even after months or years of treatment. Therefore, it may safely be asserted that the introduction of the modern wound dressing has completely revolutionized the treatment of the severer forms of talipes, and thus the way has been opened for early and absolute correction of all malpositions, whether congenital or acquired, by operations peculiar to modern surgery.

There still exists a very decided diversity of opinion among surgeons in regard to the treatment of talipes. It is maintained by some, that, with proper management from birth all cases of club-foot, without exception, can be cured, and that even tenotomy is seldom, if ever required. Some advise tenotomy soon after birth, while others condemn tendon-section as totally unjustifiable and premature, until the child is ready to walk and exercise the foot. Even in the more inveterate forms of talipes of young persons or adults, where there has been no treatment, or improper treatment, or neglect after operation, we may state that the operation as yet has not been established. It is most unfortunate that such widely different views should still exist, and it would seem that by this time some well-defined rule for

guidance should have been formulated. We have but to observe the diverse opinions, the array of surgical methods recommended, the great variety of apparatus devised, and the unsatisfactory results, to demonstrate that the question of treatment of club-foot is yet practically unsettled.

From what has been stated regarding the pathology of the deformity, it can readily be understood why there can be no successful plan of routine treatment for club-foot. Each case must be studied by and for itself, the object being to restore the deformed foot to the normal or as near to it as can be done, to retain it in this position, and to restore its function as soon as possible. Excluding all varieties of foot deformity which include valgus and calcaneus, and which give rise to little, if any, difficulty in their treatment, I shall confine myself strictly in this discussion to the two really important varieties of congenital club-foot, namely *varus* and *equino-varus*.

The other varieties of congenital talipes, which include the different forms of valgus and calcaneus, are rarely met with at birth. These deformities always present more serious nerve-lesions than are found in varus and equino-varus. The acquired forms of valgus and calcaneus are also the result of a more marked paresis or general paralytic muscular condition.

Recently, in a case of acquired calcaneus in a boy four years of age, in whom the paralysis occurred at the age of two years, I found the normal limb one inch longer than the deformed one, while the calf and thigh measurements showed a variation of two inches in circumference: the deformed foot was one inch short.

In the treatment of calcaneus and valgus the application of an apparatus, and perhaps tenotomy, is generally sufficient, and rarely will any severe operation upon the tarsus be required.

Confining our remarks, therefore, to the consideration of varus and equino-varus, we may group these deformities in two classes, as follows:

1. The simple, or uncomplicated.
2. The complicated.

1. *Simple, or uncomplicated.* In this division are those cases which, if seen at, or shortly after birth, can be rectified by traction, stretching, massage, electricity, and the use of proper apparatus. In such cases there is little or no change in the shape, or articulation, of the bones of the tarsus. Flexion and extension are nearly normal, the deformity being entirely in the soft parts. Such cases are so amenable to treatment that by the time the child is able to stand, or ready to walk, the sole of the foot can usually without much, if any effort, be placed upon the ground. Although the varus in these cases can always be corrected without operation, there may develop during this period (or it may have existed from birth) a disposition to equinus, so that when the child is ready to walk, if equinus exists, even to a moderate extent, the tendo-Achillis should be divided, but tenotomy should never be performed until this time. Afterward the child should be encouraged to walk, so as to keep the foot well stretched, the ankle motion free, and the ends of the divided tendon well apart. An appropriate, light apparatus, should be worn from early age, and subsequently until all tendency to contraction has disappeared. With careful watching, the result in such cases will usually be a perfect cure.

2. *Complicated.* But again we meet at birth with a form of talipes which I have designated as the "complicated" variety. Cases of this kind will not yield to treatment suited to the mild or uncomplicated form. In such cases we likewise find varus and equinus, and although we can usually overcome the varus, the equinus cannot be corrected; the foot cannot be brought into the right-angle position with the leg. In such it will be found that the normal depression on the dorsum of the foot, just in front of the fibula, is filled with a prominent irregular mass of bone which can be readily outlined, especially if the foot be placed in a position of extreme varus. This projecting bone, arch-shaped, is the astragalus which has been forced out of its normal position of articulation with the os calcis. The tibia and fibula are found more posterior than in the normal condition; in other words, from long tendo-Achillis contraction, exerted probably from an early period of fœtal life, a partial or complete backward dislocation of the tibia and fibula has occurred, while the astragalus, at the same time, is pushed forward from its natural position and is rotated. In this manner the equinus is produced and maintained.

In the deformity just described the leg-bones rest in part or absolutely upon the calcis, forming a new joint, while the displaced astragalus represents a sort of a wedge in front of the ankle which interferes with the joint motion, and effectually prevents flexion of the foot to a right angle.

In these cases the astragalus will be found to be the source of obstruction, and it is principally to this pathological condition that our attention must be directed.

It is beyond question, I am quite confident, that a large proportion of the unsuccessful results from operations in talipes, and the subsequent occurrence of the inveterate or severe forms of foot-deformity, are due to this condition not having been recognized or thoroughly appreciated. I am also inclined to believe that tarsotomy, tarsectomy, and the "open incision," so-called, will, if this view be correct, rarely, if ever, be required in the congenital form of equino-varus which I have de-

scribed. I have on a number of occasions in times past operated on such by tarsectomy and open incision, and although improvement has followed, yet the operation has failed to overcome completely the equinus; and subsequently I have been compelled to remove the astragalus in order to correct the deformity, to bring the foot properly on the ground, and to secure proper flexion of the joint. In all of the cases of the congenital equinus in which I have excised the astragalus, the removed bone was so altered from the normal as to be unrecognizable.

I recently sent two of these bones to Professor Leidy for examination, with a note asking him to identify them, to which he replied as follows:

"The two specimens of bone, submitted to my examination a few days since, are so altered from the normal form that I utterly failed to recognize them as being the astragalus."

Under these circumstances, it is not possible to force the astragalus between the malleoli because of its altered shape and fixed position. In other words, the altered or abnormal condition has become the normal one, and it is not possible to reconstruct the articulation. When the condition just described is present, nothing will relieve the deformity except the removal of the astragalus. This displacement of the astragalus forward, and of the tibia and fibula backward, appears to be the result of traction of the gastrocnemius, with relative weakness of the anterior muscles, having had its origin at an early period of fœtal development before the tarsal bones were ossified and their articular surfaces or facets fully formed.

The removal of the astragalus in no wise shortens the limb, because the tibia and fibula in these cases do not articulate with this bone, but with the os calcis.

We may now consider those cases of aggravated or so-called inveterate deformities, whether congenital or acquired, which have resulted from improper treatment, or from neglect after operation, or which have not had any treatment at all.

Inveterate Club-foot.—Cases of congenital or acquired equinus and equino-varus which have never been treated readily become aggravated by walking, partly by the action of the stronger muscles which are constantly twisting the foot inward, but more particularly on account of the weight of the body. The tarsus becomes more and more misshapen, the inversion increases, the sole of the foot is upturned, and soon the patient walks on the cuboid, or even on the dorsal region, where a dense bursa forms. Gradually the tarsus becomes more and more solid and unyielding, while the foot and ankle are deprived of flexion and extension.

Whether the deformity is congenital or acquired, the object will be to rectify effectually the malposition. The correction should be so complete that no disposition to contraction can be observed at the time of the operation, and I would lay down the rule that all interfering structures, soft parts or bone, whether the tarsus is considered as a whole or as individual bones, should be sectioned or excised. It will probably be found, as I have shown, that the astragalus is very commonly the obstruction to rectification in the congenital form.

When tarsectomy is proposed, it should be clearly demonstrated that the distortion is due to the anterior tarsus alone, and not to dislocation of the astragalus. If there is equinus with varus, and it is found impossible to flex the foot to a right angle, or if the ankle motion is greatly restricted, and if, at the same time, the region anterior to the fibula is occupied by the mass of bone already referred to, it is certain that the astragalus is prominently concerned in the deformity. In such cases, if the astragalus is removed the tarsus will unfold by moderate manual force, and the foot can be brought into good position; for it will be found that the space gained by removal of the astragalus will permit, to a very remarkable degree, a replacement of the anterior tarsus. It is true that occasionally there is so great fore-shortening of the skin and deep soft structures on the inner side of the foot as to interfere with the unfolding of the foot and its being brought into normal shape; and if this condition be found, it may be necessary to also divide very freely the tissues on the inner side. It should be remembered, however, that this open wound may be of considerable size, and must contract in its final healing, and so dispose to the re-formation of the varus. To obviate this, I have suggested and successfully made a plastic operation, by turning upon the wound a flap of integument from the dorsum of the foot.

The treatment of talipes varus and of equino-varus, congenital or acquired, simple, complicated, or inveterate, we may briefly sum up as follows:

1. *Simple or uncomplicated* congenital varus and equino-varus can be cured without operation other than an occasional tenotomy of the tendo-Achillis.

2. *Complicated* congenital equino-varus which is associated with dislocation or displacement forward of the astragalus, requires excision of this bone and tenotomy of the tendo-Achillis.

3. *Mild, severe, or inveterate* talipes, whether congenital or acquired, which has never been treated, or has been neglected after treatment, or improperly operated upon, may require, according to the deformity, tenotomy, excision of the astragalus or cuboid, tarsectomy or open incision, or combinations of these operations.

Operation for Excision of the Astragalus.—The operation presents no special difficulty. The

Esmarch bandage should be used. The astragalus being, in this case, merely subcutaneous, it is readily exposed by an incision, which should include the most prominent part of the bone, extending from the end of the external malleolus in a straight or slightly curved line to the base of the metatarsal bone of the middle toe. The knife is then carried around the circumference of the bone and the attachments severed, when the bone may be grasped and lifted with bone-forceps; the sub-astragaloid ligament and other tissues can be divided either with the knife, curved scissors, or blunt-hook knife devised by Lund. The tendo-Achillis should always be divided. The wound is brought together with interrupted gut-suture, and a few strands of the same are carried to the bottom of the wound to insure drainage. Before, during, and after the operation rigid antiseptic measures should be used. Immediately after the operation the foot should be capable of being placed in an easy, natural position without any tension. If there should be the slightest disposition in the foot to reassume an abnormal position, search should be made for all contracted tissues, and such should be sectioned. The line of sutures is covered with protective, over which is applied the bichloride-gauze dressing, or the mercury and zinc moist gauze; this is held in position by a wet sublimate-gauze bandage, leaving the extreme ends of the toes exposed. Antiseptic cotton, another wet, and then a dry bandage completes the dressing.

A posterior, well-padded, right-angle, flat, tin splint is then applied. Care should be taken to have the heel well down and the deformity *slightly* over-corrected. If there is no soiling of the dressings they need not be disturbed for several weeks. Usually at the end of a month the wound is firmly closed, and shortly after this, or so soon as the child makes any effort, he should be encouraged to walk, when the tin splint must make way for the ordinary talipes walking-shoe.

Tarsectomy.—That no less than eleven different forms of tarsectomy have been described for the cure of club-foot would seem to show that surgeons have not found any one of these operations giving perfectly satisfactory results. The very fact that relapses have occurred after the most carefully conducted tarsectomies, shows that probably the pathology of the deformity has not been properly understood. A year ago a boy four years of age was brought to me with double equino-varus, a typical congenital case to which no treatment had ever been directed. I performed tarsectomy, made the open incision, divided the anterior and posterior tibial tendons, the plantar fascia and the tendo-Achillis in each foot. Although a fairly satisfactory result was obtained, yet the feet could not be planted squarely on the ground when the child stood upright, nor could they be brought to a right angle with the leg. I observed that flexion was from the first markedly restricted, but hoped that in time this would be overcome.

The boy was again brought to me a year later (in March last) with marked equino-varus of both feet with great contraction on the inner side where the open incision was made. There was total inability to flex the feet to a right angle, and the obstruction to ankle motion was found upon examination to be due to a displaced astragalus. At the time of the first operation the pathological conditions which I now believe prevail in all cases of congenital equino-varus of the complicated form were not so fully recognized, and I can understand why the tarsectomies were of but little, if any, benefit. Finding that another operation would be necessary, I removed the astragalus in each foot with entirely satisfactory results.

I am, therefore, quite prepared, after considerable experience, to believe that tarsectomy and the open incision, except possibly in the inveterate deformities of more mature years or in adults, will seldom if ever be required.

To illustrate the foregoing principles, I submit the following notes of cases in which the treatment by excision of the astragalus gave results that could be attained by no other method with which I am acquainted.

CASE I. *Congenital equino-varus; unsuccessful operations in early life; excision of the astragalus; cure.*—Thomas C., aged fourteen, was admitted to the Orthopædic Hospital June 12, 1889. He had been operated upon for club-foot when nine months

FIG. 1.

Case I. Congenital equino-varus. Unsuccessful operation in early life.

old by general tenotomy, and had worn braces for several years without benefit. His condition was as follows: Left foot, congenital equino-varus with great outward displacement and rotation of astragalus, its fibular articular process presenting subcu-

taneously in the central plane of the leg. Considerable atrophy. Right foot normal, three-fourths of an inch longer than the left. (Fig. 1.)

July 16, the astragalus was excised through a curvilinear incision extending from half an inch above the external malleolus to the base of the metatarsal bone of the ring toe. The bone had to be split with cutting pliers before the sub-astragaloid ligament could be divided; otherwise the operation was easy. Tendo-Achillis divided. Catgut drain, permanent antiseptic dressing, and right-angle tin splint were used.

August 11. twenty-six days after the operation, dressed for the first time; foot in excellent position and condition; wound healed, save a very superficial ulcer.

13th. Wound entirely cicatrized.

28th. Brace applied, and he was able to walk; the foot presented no tenderness.

Fig. 2.

Case I. Condition, May, 1890.

April, 1890. Good ankle-motion; excellent use of foot and limb; position normal. (Fig. 2.)

Case II. *Congenital equino-varus (double); unsuccessful operation in infancy; excision of left astragalus; cured.*—George H., aged three years, was admitted to the Orthopædic Hospital, August 21, 1889.

Right foot: congenital equino-varus, operated upon in infancy and tendons divided, but foot greatly deformed at present.

Left foot: also operated on previously, but in much worse condition, the astragalus being rotated through nearly half a circle with its tibial articulating surface subcutaneous.

August 22. Left astragalus removed entire, without difficulty, through an incision extending in a curvilinear direction from just above the external malleolus to the base of the metatarsal bone of the ring toe. Catgut drain, permanent dressing, and right-angle tin splint.

Right foot: Open incision with extensive division of tendons.

September 3. Feet dressed. Right foot: wound closed. Left foot: slight superficial wound.

October 5. Walks well; good motion; position of foot a right angle.

May, 1890. Left foot in excellent position. Right foot, some disposition to recurrence of varus; excision of astragalus advised, and will soon be performed.

Case III. *Congenital equino-varus; excision of astragalus; cured.*—Alex. G., aged two and a half years, was admitted to the Orthopædic Hospital on September 26, 1889, with severe left equino-varus, the astragalus markedly rotated, and its tibial articulating surface subcutaneous.

September 27. The usual incision was made from the external malleolus forward, and the astragalus removed. The wound was dressed in the usual manner with catgut drain, permanent dressing, and a right-angle tin splint.

November 3. Dressed; perfect cure.

April, 1890. Present condition: position excellent; walks without lameness.

Case IV. *Congenital equino-varus (double); unsuccessfully treated by manipulation and stretching; excision of astragalus from each foot; cured.*—Phœbe A. N., from Milton, Penna., came under care, February, 1889, when five months old. The deformity was very marked, and the tarsus rigid. Under ether the feet were thoroughly stretched—neither foot, however, could be brought to a right angle with the leg—tin splints were applied, removed each day, and massage and traction used.

April 10. Stretched under ether, and applied apparatus.

October 1, 1889. No special benefit from previous treatment; upon examination astragalus of each foot found displaced forward and rotated. Operation at once performed; the bones were excised through the usual incision. Two dressings. Three weeks subsequently the child was able to stand; and in ten weeks subsequent to operation was walking without difficulty.

April, 1890. Position of feet good; result excellent; walks with freedom.

Case V. *Congenital equino-varus (double); unsuccessful treatment by tenotomy; subsequently excision of astragalus from each foot; cured.*—Leon H., aged two months, from Woodstown, N. J., was brought to the Orthopædic Hospital October 20, 1887, with marked equino-varus; both feet involved to about the same extent. Ordered manipulation, massage, and apparatus.

March 1, 1888. Condition about the same; marked equinus; tenotomy of tendo-Achillis and stretching; apparatus to be continued.

October 24, 1889. Deformity has increased; astragaloid equinus very marked; flexion of feet greatly hindered by the displaced astragalus. Operation performed this day, and the astragalus excised from each foot, with perfect rectification of position and motion.

March, 1890. In every respect the result has been most satisfactory; flexion and extension, and position of the feet excellent.

CASE VI. *Congenital talipes equino-varus; unsuccessfully treated by massage and apparatus for three years; excurvation of the knee; astragaloid equinus; excision of astragalus; cured.*—Alvin W., aged four years, no family history of deformity, was brought to the Orthopædic Hospital in February, 1886. He was then but a few months old; there was marked equino-varus of the right foot; a weak ankle and slight valgus of left foot. Traction, massage, and an apparatus were ordered.

February 20, 1890. Returned to hospital with marked equino-varus, and unable to flex the foot; astragalus displaced; tendo-Achillis rigid. The child, finding it impossible to place the sole of the foot on the ground, had gradually developed excurvation of the knee, which allowed the heel to come down.

22d. Astragalus was removed by the usual incision; tendo-Achillis divided; gut ligature and drainage. Dressed on the fifth and again on the twenty-third day, when the union was firm, with perfect position and good motion.

April, 1890. Result most satisfactory, both as regards position and good motion.

CASE VII. *Congenital equino-varus (double); stretching; excision of astragalus from each foot.*—Raymond J. P., aged fifteen months; has been able to walk for several weeks. No treatment has ever been attempted except daily stretching. Came under my care March 22, 1890.

Present condition: right foot, varus and equinus marked. Impossible to flex either foot to right angle. Astragalus displaced and subcutaneous. Left foot, more severe equino-varus; otherwise, condition the same as in other foot.

March 22. Excision of astragalus and division of tendo-Achillis in each foot. Feet brought to perfect position and placed upon right-angle tin splints.

Present condition most satisfactory.

CASE VIII. *Congenital talipes equino-varus (double); tarsectomy and open incision; failure. Second operation one year later; astragalus excised from each foot; cured.*

Wolf S., aged five years, was admitted into the Orthopædic Hospital in February, 1889, with a very marked deformity of both feet. (Fig. 3.)

March 10. Tarsectomy and open incision, division of tendo-Achillis, of anterior and posterior tibial tendons and plantar fascia.

May 1. Discharged in apparently fair condition of improvement; directed to wear braces and to continue stretching.

March 20, 1890. Re-admitted with aggravated equino-varus. Tarsus rigid; astragalus evidently the cause of the deformity; very limited amount of joint-flexion; unable to stand alone.

22d. Excision of the astragalus from each foot. The bones were found quite anterior to the tibia, and rotated. The usual incision, crossing the most prominent subcutaneous part of the astragalus, was made; gut drain; right-angle tin splints. After the excision the feet could, without the least difficulty, be placed at a right angle with the leg.

FIG. 3.

Case VIII. Double congenital equino-varus, March 1, 1889. No previous treatment.

April 26. Position of the feet perfect; ankle-motion good; cure perfect. (Fig. 4.)

May 10. Walking without apparatus and with ordinary shoes; limbs straight; feet turn out.

FIG. 4.

Case VIII. Condition after excision of each astragalus. Feet at right-angle to legs

CASE IX. *Congenital talipes equino-varus; manipulation, stretching, and apparatus; no improvement; excision of astragalus; cure.*

Harry W., aged sixteen years, was admitted to the Orthopædic Hospital, April 14, 1890. The right limb normal. Left, severe equino-varus and marked atrophy of entire limb; for many years has been walking without any apparatus. Ankle very rigid; general atrophy of the limb. The right thigh measures in circumference fifteen and one-half inches; calf, eleven and one-half inches.

The left thigh measures ten inches; calf, eight and one-half inches. The left foot is much shorter than the right.

April 19. Astragalus excised through usual incision; tendo-Achillis divided; foot placed without tension in normal position; usual dressing: catgut drain; right-angle tin splint.

May 10. Dressed; position excellent; superficial ulcer.

Case X. *Congenital equino-varus (double); unsuccessful operations in infancy; deformity excessive; excision of astragalus, cuboid, cuneiform, and part of the scaphoid.*

Dorothea R., aged seven, from Towanda, Pa., was admitted to the Orthopædic Hospital, April 22, 1890. General health good; no family history of deformity; weight, forty-six pounds. When five months old was operated upon by general tenotomy, stretching, and fixed dressings. The feet became inflamed and ulcerated; all treatment was abandoned; contractions increased; subsequently apparatus was applied and worn for some months. During the past three years has had no treatment.

Condition on admission.—The thighs, legs, and feet markedly atrophied and spindle-shaped; thigh- and leg-bones small; feet more solid and deformed than I have ever known at such an age. Patient walks on the cuboid bones: great contraction of all the soft parts, including the sole and inner side; ankle-joints apparently ankylosed.

April 26. Right foot; the usual incision made for astragalus excision. The tarsus was found so dense and distorted and the bones so firmly wedged that it was with the greatest difficulty that the articulations could be identified.

The astragalus, cuboid, external cuneiform, and a portion of the scaphoid required removal, in order to bring the foot to a right angle with the leg. The tendo-Achillis was divided; likewise the plantar fascia and the flexor tendons of all the toes. The wasting and contraction of the soft parts on the inner side and the sole of the foot presented great impediment to rectification. The left foot required exactly the same treatment. The wound was closed by interrupted gut-sutures, drained by a few strands of same material, and dressed in the usual manner. The feet were placed upon right-angle, well-padded tin splints.

May 12. Doing well; has not been dressed since the operation; feet in excellent position.

Résumé.—The records of these cases present fifteen excisions of the astragalus for congenital equino-varus upon ten patients, all males with the exception of one. Five had been unsuccessfully treated in infancy or early life by tenotomy, tarsectomy, or otherwise; in four cases both feet were operated upon at the same time. Four of the patients were under two years; the others were, respectively, three, four, six, seven, fourteen, and sixteen years old. The line of incision in the operations extended from half an inch or so above the external malleolus to near the base of the metatarsal bone of the fourth or ring toe, crossing the most prominent part of the astragalus; the tendo-Achillis was always sectioned. No vessel required ligation. The peronei tendons were not involved in the operation. A few strands of catgut were inserted in the wound to secure drainage. Strict antiseptic precautions were observed before, during, and after the operation. The limb was placed upon a right-angle tin splint and kept elevated for a day or two. Immediate union followed; the primary dressings were not disturbed before the end of the third, generally in the fourth, week.

Although, perhaps, sufficient time has not elapsed to give a positive opinion as to all of these cases, yet, so far, the results have been much more satisfactory than in any former operations for similar deformities in my experience.

I believe that we have more reason to expect permanent correction of the deformity after the operation of excision of the astragalus, from the fact that the cause of the obstruction is removed, so that the foot can be brought to a right angle and the whole of the sole of the foot can be normally placed upon the ground when the patient stands. The motion of the joint is also increased by the removal of the bony wedge which so seriously interferes with flexion. There has not been in any case a tendency to ankylosis nor any tenderness or want of strength in the ankle as a result of the operation. If I have correctly appreciated the pathology of these cases, I think that we are warranted in claiming that, by the means proposed, better and more permanent results will be obtained than by any other method which has been devised for the relief of these complicated forms of club-foot.

It is well, however, to bear in mind that no matter what form of operation is performed for the correction of talipes, nor how perfect may be the immediate result, a disposition to recurrence of the deformity may continue for a long time from the persistent unequal muscular action, which demands watchful care to insure a permanent successful result.

THE RELATION OF PERIPHERAL IRRITATION TO DISEASE; CONSIDERED FROM A THERAPEUTIC STANDPOINT.[1]

BY SIMON BARUCH, M.D.,

PHYSICIAN TO MANHATTAN GENERAL HOSPITAL, AND TO THE NEW YORK JUVENILE ASYLUM, ETC.

The most important element in the discussion of this question is the influence of its decision upon our therapeutic procedures.

Whether peripheral irritations be etiological factors by reason of sympathetic effect, as was formerly

[1] Discussion at stated meeting of New York Academy of Medicine, May 1, 1890.

taught, or, as a more refined pathology and more scientific inquiry into pathological processes claim to have ascertained, it be due to reflex agencies acting through the spinal cord, the chief aim of our therapeutic endeavors must be at the point of irritation. The removal of the source of peripheral irritation becomes imperative. If, on the other hand, as Dr. M. Allen Starr has correctly pointed out and as the general practitioner but too often has occasion to observe after much bootless attacking of peripheral disturbing causes by specialists, many so-called neuroses are really but the manifestations of a slight or serious defect of control by the higher centres due to their impaired nutrition and consequent impaired activity, the course of the medical attendant must be clear.

Who shall decide these different problems which now more than ever press for solution?

The method of arranging a symposium on the great medical questions of the day must be of advantage. It brings out prominently the elements of each question as viewed from different standpoints, if the essayists are selected for the diversity as well as the honesty of their respective views.

It was a wise suggestion, too, of Dr. Jacobi to afford the general practitioner a hearing on the subject offered for discussion, for he stands, as it were, upon neutral ground, watching eagerly the friendly contests of his colleagues and co-laborers, the specialists, and appropriating the wheat as they sift it from the abundant chaff by the threshing of contending views.

Therapeutic questions have ever possessed a fascination for me. In the course of the past thirty years it has not infrequently been my privilege to observe the budding forth of plausible theories, to watch them as they developed into lusty plants, only to see them blighted when the clear light of strict clinical test beat upon them.

When the lamented Hack called the attention of the profession to the attractive theory of reflex neuroses traceable to the nose, I was, although he offered us such positive clinical illustrations, somewhat reluctant in recognizing the validity of his claim. Some of the arguments which were brought against the idea of sensitive areas in the nose as the cause of reflex troubles of diverse and utterly incompatible characters confirmed the therapeutic scepticism which is the natural outgrowth of advancing years, and the doubts thus aroused were somewhat strengthened by the enthusiasm of the author. But a case presented itself shortly after reading Hack's original pamphlet which enlisted my interest. A man aged twenty-four years was brought to me by Dr. L. Peiser, with the following history:

He had been complaining for one year of a "sticking pain on the right side of the neck" about the apex of the carotid triangle. This pain was so severe at times that it deprived him of sleep. He also suffered from a dry cough and, what annoyed him more, violent attacks of sneezing ten or twelve times in succession, recurring four or five times a day. His acquaintances twitted him because he "sneezed like a cat." His appearance was worn and dull. The right lower turbinated covering was cavernous and doughy, and touching the septum which presented numerous sensitive spots. The lower turbinated on the left side also touched the septum and was sensitive but not doughy. The uvula was elongated. Posterior rhinoscopy revealed spongy hypertrophies on the lower turbinated. The right anterior turbinated swelling was thoroughly cauterized with the galvano-caustic point, under cocaine. Ten days later he claimed an improvement; two sensitive spots on the septum were now cauterized. Six days later pains in the neck had disappeared. Cough continuing, a portion of the elongated uvula was cut off and the left lower turbinated was cauterized. After two more cauterizations of sensitive spots on the septum, his nasal fossæ were clear and free. Sneezing, cough, and pain subsided.

The attacks of sneezing in this case were probably due to mechanical irritation, for, as Hack has shown, and as I have frequently observed, the "erectile" turbinated coverings are subject to enlargement and to diminution by mental and physical causes. The cough, too, was probably due to the elongated uvula. But the pain in the neck was probably reflex.

It is just as important to adopt local treatment, whether the peripheral irritation produces symptoms through mechanical or through reflex channels. But it is well to differentiate these conditions for the sake of scientific accuracy, as was done in this case. The first positive case which removed my scepticism on the reflex influence of nasal peripheral irritation is a cure of true epilepsy, the only one which has ever occurred under my observation:

A. K., aged sixteen years, a robust boy, had been suffering from distinct attacks of *grand mal* since the summer of 1884.

The free use of bromide, by my friend, the late Dr. Wm. Frothingham, diminished the number of attacks and finally gave immunity for one year. But they returned with greater frequency, and continued despite increased quantities of bromide. Dr. Frothingham having referred the case to me on April 1, 1886, it occurred to me that an enchondroma on the left side of the anterior portion of the septum, which filled the entire fossa in front, forcing the ala far beyond its normal line, might be a peripheral irritant bearing etiological relations to the epilepsy. After failure with the galvano-cautery, as advised by Woakes, I removed the entire growth with a Bosworth saw. The bromides were continued until September, 1889. He had an attack a week after the operation, but since then he has

. been entirely exempt, although during the past seven months he has taken no bromides.

An immunity from attacks for four years may probably be regarded as a recovery from the disease. Similar cases are on record in recent literature, the most recent addition being six cases of epilepsy reported by Schneider.[1] These cases cured, after the failure of active bromide treatment, by removal of pathological conditions in the nose, furnish interesting reading to those who are sceptical regarding the influence of peripheral irritation in disease.

A disease like epilepsy, in the presence of which we stand almost helpless, demands the utmost scrutiny of search for possible etiological factors.

There are a sufficient number of cases recorded by reliable observers to warrant us in adding the nose to the field of possible points of reflex irritation. Empirical though such treatment may be and probably inexplicable upon strictly scientific principles, it behooves us to remove all pronounced abnormal conditions existing in the nose, *as an auxiliary therapeutic measure*.

With regard to asthma, migraine, trigeminal neuralgia, and minor nervous affections, the conditions are different.

The nose presents a field for thorough study of the question at issue, and it should be utilized to the fullest extent. Unlike the ovaries and urethra or other internal organs, we may subject it to tests which are impossible in these organs. It is not difficult to ascertain the presence of sensitive areas in the nose, even if the patient's attention has not been directed to them by actual symptoms. If irritation by the probe produces the paroxysm of migraine, asthma, or neuralgia, we have evidence that can be obtained from no other organ. And if in addition to this, we succeed in removing the attack, either artificially or spontaneously produced, by complete cocaine anæsthesia of the sensitive areas, the etiological connection is demonstrated beyond a doubt, and the treatment is clear. In a recent paper on asthma, Professor Dielafoy of Paris, recommended a cocaine application to the nose as the first step in the treatment. This is a wise suggestion, for if, as our *confrères*, the rhinologists, claim with some show of reason, nasal irritation may be the starting-point of an asthmatic paroxysm, the latter must surely be abated by inhibiting the sensitiveness of these spots. But here an error may creep in. It will not suffice simply to brush the nose with a two-per-cent. solution of cocaine. A bulb-pointed syringe or atomizer with numerous fine openings introduced just within the nostrils, would distribute half a drachm of a four-per-cent. solution of cocaine over the accessible portion of the nasal fossa. If the patient will press the bulb or piston of the syringe during expiration, hold his head downward and avoid swallowing the fluid, no possible harm can ensue, while complete anæsthesia of the entire nasal tract would be attained. If an attack of asthma or neuralgia be averted by such anæsthesia the proof is clear. How many of our enthusiastic friends apply such a test or any other test in these cases? Except the *post hoc ergo propter hoc*, than which none is at times more misleading, we have in these tests a perfectly available method, which I trust will be more frequently resorted to, of discovering the actual connection between peripheral irritation and disease at a distance.

I am of the opinion that the so-called peripheral irritations should only be treated as etiological factors, if they manifest themselves to the patient.

This holds good, however, of all organs except the nose. The latter is,—as the epithelium covering its lining mucous membrane indicates, a respiratory as well as an olfactory organ. As an olfactory organ its function may be greatly disturbed or entirely lost without actual damage to the economy. Even as a respiratory organ its functions may be interfered with, without much embarrassment, because the mouth furnishes a vicarious channel for the entrance of air: hence only when very positive stenosis exists does the system rebel and call the patient's attention to its presence, by embarrassment of the respiration or other symptoms. Sensitive areas, swollen and cavernous turbinated coverings, polypi, etc., may exist within the nose, as the cases I have cited witness, without being sufficiently recognized by the patient to call the physician's attention to them. It therefore becomes our duty to search for these abnormal conditions in all those functional nervous disturbances which have been reported as possibly connected with nasal irritation. The tests I have referred to are then readily applied, and the treatment is rendered more effective and less difficult than in many other disturbances. A word of warning may, however, be not inopportune at this point. Operations on the nose are not so free from danger as they have often been represented by some enthusiastic specialists. I am personally cognizant of two cases, in which deviations of the septum were removed by the saw; one with serious, the other with fatal results. The first, operated on while apparently in good health, by one of the most noted rhinologists of the present time, suffered from hæmorrhages and septic fever, which seemed to be the starting-point of a state of cachexia lasting over a year, during which a malignant and fatal disease of the stomach developed. The second case, also in good health when operated on by one of our most active septum-sawers, whose skill cannot be impugned, awoke the night succeeding the operation with vomiting of blood and with

[1] Berliner klin. Wochenschrift, October 28, 1889.

epistaxis. He fell ill, and was attended for three weeks by no less than eleven physicians and surgeons. When I took charge of him, the gentleman who had operated gave an obscure history in the patient of feeble heart, loss of appetite, and great apprehension of a fatal issue. I found the urine had been reduced below 20 ounces daily, without microscopic or other evidence of renal disease. An unfavorable prognosis was given. Dr. A. Jacobi, who had previously seen the patient, was called in consultation. The patient died thirty-six hours after I first saw him, simply from exhaustion due to loss of blood and subsequent inanition. A post-mortem discovered no trace of organic disease. There is no doubt in my mind that this death was directly due to the operation for deviated septum, which had been properly and skilfully done, *for relief of embarrassment to respiration.*

When you are told, by our friends, the rhinologists, that the operation for deviated septum, if skilfully performed, is free from danger, bear in mind this testimony of a general practitioner, and let it not be done except for good cause.

In other organs the difficulty of discovering points of irritation is not so marked as in the nose, because interference with their functions becomes more or less burthensome, and in a large proportion of cases calls for remedy.

The eye, for instance, does not brook infringement upon its normal condition without protest—a protest which may or may not be heeded, according to the intelligence of the patient and his capacity for resisting encroachments upon normal functions. Here it is important to inquire cautiously for symptoms, lest by leading questions we be led astray. But here too the connections, if such exist, between peripheral irritation and the existing functional nervous disturbance may be traced, and it should be clearly traced ere the diagnosis is regarded as exact.

Surely nothing is easier for the general practitioner than the inquiry for eye-strain in connection with or independent of the attacks whose causative relations he is endeavoring to fathom. And, if he is in doubt, nothing is easier than to refer such a case to his friend the ophthalmologist. This has been my constant practice since it first suggested itself in my own case, which may be of interest in this connection. Up to within nine years ago I was a martyr to migraine, suffering one or more attacks weekly, which disabled me from work. Although I was conscious of a difference in the refraction of my eyes, I was assured by two eminent oculists that the difficulty was a simple myopia affecting the right eye, with which it was not advisable to meddle. On coming to New York and taking a course of instruction on the eye and ear, I discovered a double astigmatism. Dr. R. H. Derby was kind enough to make a thorough examination of the refraction under homatropine, by which he discovered a high degree of myopic astigmatism in the right and a minor degree in the left eye. The correction of the error of refraction not only endowed me with perfect vision, but the agreeable discovery that the migraine was removed was an additional and unexpected result. Not a single attack has occurred since the glasses were adjusted.

If we do not succeed in relieving the patient of the functional nervous disease for which the ophthalmic examination was advised, we may at least be content that no damage has been inflicted by the correction of any error of refraction that may have caused distress from eye-strain.

This is quite a different matter, however, from the mutilations which have been recently recommended by some of our *confrères.* The mournful record of these mutilated eyes and disappointed patients is indeed, as has been remarked by another, a sad chapter in the history of this subject. The fact that the novel view that "asthenopia," from which nervous diseases of all kinds are now said to result, "is chiefly dependent upon muscular insufficiencies, and is generally to be relieved by operations upon these muscles," is entertained and urged by only a very small number of men who stand alone in this country, and that this idea has not received the slightest recognition in Europe, where the opportunities for testing its correctness are so abundant, appeals to the general practitioner as a cogent reason against its acceptance. The Neurological Society of this city has fairly weighed the arguments advanced by these innovators, and now Dr. Roosa has added one of those valuable practical observations, of which he is so admirable an adept, which must remove the question from the arena of discussion. He has shown us that, among over one hundred healthy persons, 84 per cent. presented a want of muscular equilibrium, so-called heterophoria, and that, moreover, a great deal depends, as has been well-known since Graefe's time, upon uncorrected astigmatism. I was somewhat surprised that Dr. Roosa deemed the refutation of this novel and unsubstantiated theory a cause worthy of his steel. But he has offered us a clinching argument which must lay this all too lively ghost to everlasting rest.

From a therapeutic standpoint the eye as a source of peripheral irritation demands as careful and painstaking investigation as the nose. I am convinced that both promise satisfactory therapeutic results. But our efforts must not be indiscriminate. *Vit nocuisse* should be our motto so long as uncertainty haunts our course. Fortunately we have in these organs means for ascertaining positively the existence of points of peripheral irritation and of reme-

dying them harmlessly. I plead for the more general adoption of these tests before active treatment is adopted.

The sexual organs as sources of peripheral irritation have been ably discussed from the gynecological standpoint.

From a therapeutic standpoint I desire simply to plead for the same principles that I have enunciated regarding the eye and nose. Here, however, we meet greater difficulties. The male genital organs are more accessible to investigation and treatment than those of the opposite sex. Alexander Peyer, our own Otis, and many others have studied this subject from the specialist's point of view. They have offered us clinical data which cannot be controverted. But let us proceed cautiously, and always bear in mind the motto, "*Nil nocuisse.*" Mutilation of these important organs must be avoided, unless the existence of a point of peripheral irritation is clearly established. We have no tests here as we have in the nose and eye, so every other means must be exhausted before local surgical treatment is resorted to. Another point of therapeutic importance is to be remembered, viz., the danger of directing the patient's attention to the sexual organs as a possible cause of his functional troubles. Such a course is almost certain to increase the latter.

The existence of peripheral irritation in the utero-ovarian system has long been a vexed question. While I am convinced that a lacerated cervix is frequently an etiological factor of pronounced type, and while I regard the removal of the local pathological conditions connected with the latter as a *sine qua non* to the improvement of the health of many suffering women, I am also convinced that these lesions rarely if ever give rise to the reflex functional nervous troubles that have been attributed to them. The latter may almost invariably be traced to conditions of general ill health and anæmia, resulting from the local processes which give rise to muco-purulent discharges, to infection from raw surfaces on the cervix, and to interference by pain with comfortable locomotion, rather than to the pressure of cicatricial plugs, etc. These views I have fully set forth in a paper on the therapeutic significance of the cervical follicles,[1] and I must now be content with this simple reference to a subject which has given rise to more acrimonious and bootless discussion than even the insufficiencies of the ocular muscles.

The idea of the connection of ovarian irritation with functional nervous diseases is coeval with the history of medicine. Since gynecology has become a full-fledged offspring of medicine this question has persistently clamored for solution. There has been so wide a schism in the ranks of the special worker in this branch, a schism which is happily narrowing to a more conservative point in recent years, that a general practitioner may well be excused from expressing his views, except to urge respectfully the warning, "*Nil nocuisse.*" I have searched the literature of this subject industriously for the clinical proof that the removal of the uterine appendages has been instrumental in removing pronounced functional nervous diseases. While I am convinced that the ablation of *diseased* ovaries and tubes must and does contribute to the improvement of health in some women by removing foci of infection, distress, and pain, and by removing a barrier to exercise and to the pursuit of the duties of life, I cannot bring myself to the belief that the removal of ovaries or tubes not presenting palpable and well-defined pathological changes is ever called for; and I deem such a procedure an outrageous violation of the highest aims of our calling, which demands the condemnation of every decent physician.

There are many other points of peripheral irritation whose relation to disease demands discussion. As one speaker has referred somewhat contemptuously to peripheral irritation as productive of nervous diseases, it may be well to mention that we have the authority of Professor Thomsen, of Berlin, for the statement that even serious psychoses may be traced to peripheral irritation. In the *Charité Annalen* for 1888 he gives the histories of five cases of reflex psychoses resulting from wounds of the head, with concentric narrowing of the field of vision and unilateral hallucinations; and two other cases in which scars in the periphery produced epileptic attacks, and later also psychoses, which were cured by excision of the scars. All these patients suffered anæsthesia or hyperæsthesia, and in all the extent of the field of vision was an index to the amount of the psychical disturbance.

The relation of peripheral irritations existing in the gastro-intestinal tract to diseases elsewhere, has been recognized from the earliest time of medicine as an empirical observation, by which the harmful practice of indiscriminate purging has been upheld. Our literature abounds in well-defined clinical evidence upon this subject. Among the most recent and interesting observations I find one which in this day of over-zealous specialism may serve as an illustration of scientific conservatism. Professor Gussenbauer has published[1] twenty-eight cases of intermittent trigeminal neuralgia, which were referred to him for surgical treatment, and among which he found only four that required surgical interference. The remaining twenty-four yielded to careful attention to existing intestinal torpor. Some of our enthusiastic specialists would do well

[1] Prager medicinische Wochenschrift, No. 3, 1886.

to emulate the example of this conservative surgeon and ponder well and long ere they inflict lasting deformities upon the patients committed to their care.

Nothnagel has clearly shown in his *Klinik für Darmkrankheiten* that intestinal activity depends upon the functionating capacity of the intestinal glands, and that many cases of constipation may be traced to the diminution of automatic action in the nervous apparatus of the intestines. That pathological changes in the ganglia of the intestinal muscles, producing constipation, may convey nervous impulses through the sympathetic to the cerebro spinal system, and then produce abnormal sensations, has been often practically demonstrated.

Nothnagel believes that hemicrania from constipation is due to a venous stasis in the intestines, which impairs the functions of the latter by reason of an insufficient supply of oxygen, so that intestinal irritability or automatic activity is diminished. The latter produces abnormal excitation of the cerebrospinal system, resulting in an irritation or paresis of the vaso-constrictor fibres of the cervical sympathetic, which in turn produces the vaso-motor phenomena of hemicrania.

Sciatica, formerly supposed to be due to pressure from fæcal masses in the sigmoid flexure, may be similarly explained. This brief reference is made in order to illustrate that many functional nervous conditions may be removed by the old-fashioned and rationally explicable treatment of constipation, and to emphasize thereby the lesson that careful and industrious search for foci of peripheral irritation should be made *in every direction* before the eyes and nose, the urethra, or worst of all the uterus and ovaries are attacked and mutilated.

In conclusion, permit a general practitioner who has endeavored by many years' service in the eye, ear, throat and gynecological departments of our city dispensaries, and by industrious attendance upon the clinics of our metropolitan hospitals, to keep himself abreast of the advances of special departments in medicine, to sum up his views on the therapeutic significance of peripheral irritations, as follows:

1. The existence of peripheral irritation as an etiological factor is well established.

2. There need be no conjecture in the search for such causes of functional nervous diseases in many cases, because we have means, in at least the more recently discovered sources of peripheral irritation, the eye and nose, of detecting and testing their existence.

3. All harmless methods of treatment should be exhausted before mutilating procedures are adopted.

4. Whenever there is a doubt the local condition should receive the benefit of that doubt and treatment should be directed to the improvement of the general health, the re-establishment of defective secretions and to the removal of the patient from unfavorable environment.

AN OVARIAN CYST, COMPLICATING PREGNANCY; OBSTRUCTING LABOR AND BECOMING GANGRENOUS IN THE PUERPERAL STATE.

BY BARTON COOKE HIRST, M.D.,
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA

MRS. S., married for thirteen years, had one child twelve years ago, when she was delivered by forceps. The lying-in period was complicated and since that time the patient has been in bad health. She was told by one physician that there was backward displacement of the womb with fixation, and that she could never again be impregnated. Another said there was a pelvic tumor. A gynecologist of New York believed the tumor to be a fibroid and prescribed fluid extract of ergot in teaspoonful doses; this was taken three times a day for two months, and afterward in daily doses of a teaspoonful for two years until last July, when the medicine was discontinued on account of the nausea and general distress which it produced. After this time the menses failed to appear, and there soon developed all the presumptive signs of pregnancy; there occurred at this time several sharp attacks of abdominal inflammation. A physician who was then consulted took such a gloomy view of the case that the patient became thoroughly alarmed, and, having heard of Dr. S. Weir Mitchell as a famous physician, travelled to Philadelphia to consult him in regard to her condition. She was bitterly disappointed when Dr. Mitchell refused the case and kindly referred it to me. On examination I found an abdominal tumor corresponding in size to the uterus at the seventh month of gestation. Palpation detected the outline of a fœtal body and intermittent contractions of the tumor walls. Fœtal heart-sounds were plainly heard. On vaginal examination the cervix was discovered, with some difficulty, high up and far forward, directly over the symphysis pubis. Back of it the posterior vaginal vault projected downward with an even dome-like shape to within an inch of the vulva—too soft for a fibroid, too firm for a cyst. On balancing the fœtal head between the fingers placed above the symphysis externally and those within the vagina, the impact upon the latter was so distinct and the head entered the pelvic inlet so readily that the idea of sacculated uterus occurred to me. The diagnosis rested between this condition and some form of tumor blocking up the pelvis, with the stronger inclination on my part to the former opinion. Arrangements were made to induce labor two weeks before term by dilating the cervical canal and then to proceed according to the indications. When the dilatation was sufficient to insert a finger in the uterus the nature of the trouble was discovered to be, not sacculation of the uterus, but a tumor in the pelvis which gave an indistinct sensation of fluctuation.

On the chance of the tumor containing fluid an aspirating-needle was plunged through the vaginal vault and eight ounces of a thick, grayish sebaceous-like liquid slowly flowed into the aspirator bottle. This reduced the tumor in size sufficiently to permit combined version and the extraction of an infant, alive but so deeply asphyxiated that it could not be revived.

The mother did perfectly well for four days, when the temperature began to rise. The fever at first was slight, but gradually increased until on the tenth day it was evident that there was serious trouble. Being obliged to leave town on that day, I requested a colleague to operate for me. Returning a week later, I found the operation not yet performed and the patient in a desperate condition. She had high fever, was reduced to the last degree, and had a rapid, fluttering, almost imperceptible pulse. She certainly had not more than twenty-four hours to live. A laparotomy was immediately done, under partial anæsthesia. A large tumor with dark-colored walls was seen to the right of and behind the uterus, immovably fixed by dense adhesions. It was punctured and discharged several pints of horribly fœtid fluid mixed with putrefying solid particles. Enucleation of the tumor was out of the question. The empty sac was stitched to the abdominal walls and drained, the peritoneal cavity was well washed out, the lower part of the omentum, congested, œdematous, and thickened to about one and a half inches, was amputated, and the abdominal wound closed without drainage. As there was a constant discharge of fœtid pus from the sac, the abdominal wound was simply dusted with iodoform and covered with a piece of absorbent cotton which was changed every half hour, as no occlusive dressing could have been kept clean. The wound healed by first intention. The day following the operation the woman's temperature was normal. There have been a few rises of temperature during convalescence, due to imperfect drainage of the cyst. This has been overcome by a counter-opening made into it through the vault of the vagina. The case at present (eight weeks after the operation) bids fair to end in a speedy and complete recovery.

CLINICAL MEMORANDA.

THERAPEUTICAL.

Is Aconitine "Always Unsafe Internally"?—The above question, which I shall endeavor to answer in the negative, was suggested to my mind by noticing in the table of doses in the *National Medical Dictionary* the statement that aconitine is "always unsafe internally," and also that the dose is from "$\frac{1}{400}$ to $\frac{1}{300}$ of a grain."

From actual experience I am convinced that aconitine is far from being an unsafe internal remedy, but that, on the contrary, it is one of the most valuable and safe therapeutical agents, if given in proper doses, and with the judgment that is always necessary in administering the alkaloids. Like all drugs of its class, it is very powerful; but this makes it the more useful, as the dose is consequently small, and its physiological and therapeutical effects are rapidly obtained. For nearly three years I have used aconitine in place of all other preparations of aconite, and in no instance have I observed any dangerous symptoms follow. I have given it, both by the mouth and hypodermically, in doses ranging from $\frac{1}{500}$ to $\frac{1}{160}$ of a grain, and I would have no hesitation in giving $\frac{1}{100}$ of a grain in proper cases. The latter dose would correspond to about one grain of aconite root.

To employ therapeutic agents to the best advantage, the physician must be able to prescribe the exact dose required. This is impossible with drugs of variable strength. That a crude vegetable drug will vary greatly in this respect is a fact that all must admit, and, consequently, drugs in this form are now comparatively little used. They have given place to solid and fluid extracts which are more uniform in strength. These, ere long, must give place to remedies whose strength has been definitely fixed by assay. It is unreasonable to suppose that the active principle of any drug is an unsafe remedy, for it is to this principle that all drugs owe their virtue. True, the active principles are a great deal more powerful for good or harm; and, consequently, it is necessary to handle them with more care and judgment. By using aconitine we obtain a more rapid and decided effect than we can with aconite, and one that is preferable in many respects.

In concluding this note, I wish to say that I believe, if any intelligent physician will give the active principles an unprejudiced trial for one year, at the expiration of that time he will agree with me that they are far more desirable than any other form of medication, and that, if handled with care, they are far less dangerous.

Calamine, Ark.

HOSPITAL NOTES.

EXCISION OF A BRANCHIOGENIC CYST. RADICAL CURE OF INGUINAL AND VENTRAL HERNIA. OPEN OPERATION FOR VARICOCELE.

Abstract of a Clinical Lecture delivered at the Roosevelt Hospital, New York.

By CHARLES McBURNEY, M.D.,
ATTENDING SURGEON.

A man thirty-five years old with a large cystic tumor on the front of the neck was the first subject for operation. This tumor was perfectly round and smooth and projected just beneath the symphysis and body of the jaw, with a deep attachment on the left side beneath the edge of the sterno-cleido-mastoid muscle. It was about four inches in diameter. The tumor had been first noticed when the patient was six years of age, but had caused no disturbance of function and no great discomfort, but had grown very much during the last four years. Dr. McBurney said that it was a branchial cyst, produced from the remnant of a fœtal branchial cleft, one of the four openings between the branchial arches, which are seen at the end of the first or the beginning of the second month of fœtal life. Owing to defective closure of these clefts embryonic structure becomes included in the tissues of the neck, and this is capable of

producing large and very serious cysts. Although their origin is so remote, it by no means follows that the development of the tumor is noticed at birth or even soon after, for they may not make their existence known for many years. They are lined with epithelium, sometimes ciliated, but usually of the tessellated variety. This epithelium is the element which has made it so difficult to obtain a complete cure; for, so long as a portion of this epithelium lined cyst remains, unless there is sufficient active inflammation after the operation to destroy the lining there will most probably be a recurrence.

There was a difference in the situation of this cyst from that of a cyst of the thyroid gland; for the thyroid gland was below the site of the tumor, which did not participate in the movements of deglutition. There was no pulsation to be felt in the tumor.

Dr. McBurney said that in the treatment of this condition all such methods as the seton, which have for their object the establishment of inflammatory action within the sac for the purpose of obliterating it, should be discarded. Evacuation of the contents of the sac and the injection of tincture of iodine are inefficient and unscientific procedures; for the cysts often have prolongations running deep into the tissues of the neck which cannot be reached by such means. Treatment by simple incision and drainage has so often failed that it holds out no special inducements. If the wound were packed with gauze the obliteration might be only superficial, and a second operation is much more difficult on account of the inflammatory thickening of the tissues. Some cases of excision of the cyst are very simple, the tumor shelling out with comparative ease; while others are so difficult as to force the boldest operators to abandon the operation. One difficulty frequently met with is the close attachment of the cyst to the jugular vein. This vein is readily displaced, and is often emptied of blood by the tension made by the tumor, so that a safe dissection of this region is extremely difficult. The plan proposed in this case, which was apparently an easy one, was to dissect down to the tumor and then decide upon the propriety of performing a complete excision. If this were found to be too dangerous, the exposed portion would be cut off, and the wound allowed to granulate in the hope of securing obliteration of the remainder.

A thick reddish-brown fluid, which was first removed by hypodermic puncture, under the microscope showed epithelial cells, fat and cholesterin. An incision was made in the median line over the whole extent of the tumor, the overlying tissue being found very vascular. There was not a single and easily dissected capsule, but rather a number of capsules, each one of which partly surrounded the mass. There was no attachment to the jugular vein, although this vein lay immediately under the left edge of the tumor, which was removed entire without any special difficulty. The wound was irrigated with bichloride solution (1:2500), and a few small vessels tied. A rubber drainage-tube was inserted at each side through separate openings and the wound was closed with a continuous silk suture. A final irrigation and the application of antiseptic dressings completed the operation.

Case II.—The next patient was a young and healthy woman with a tumor in the right groin. The tumor was reducible, and had never been strangulated or inflamed, but had been very painful. It proved to be an indirect inguinal hernia coming well down into the labium. Dr. McBurney said that the radical cure of hernia was especially desirable in women, and he did not acknowledge any contra-indication to the performance of his operation for radical cure, except alcoholism or some advanced chronic ailment like Bright's disease, which would make one hesitate to do any important operation. The mortality from the operation had been extremely low, he having lost only two patients out of a large number, and both of these developed acute alcoholism very soon after the operation. His cases had never had peritonitis, hæmorrhage, or general septic infection, although some of the herniæ had been large and the intestines had been handled pretty freely. He does not consider some other methods of radical cure equally safe; for, in his operation there is no tissue deprived of vitality included under the skin or sutures, and no opportunity for concealed sepsis. Brilliant as had been the results of Macewen's method, he could only regard it as founded on unsound surgical principles. The return to a concealed position beneath the abdominal wall of a tissue like the sac which had been dissected out and deprived of its vitality he could not endorse.

The incision was begun just beyond the situation of the internal ring following the line of the canal as far as the pubes, and the dissection was continued at the upper part until the external oblique aponeurosis was exposed. Then the remainder of the incision external to the sac could be completed in safety. This exposed the pillars of the ring and the hernial sac. The sac appeared to be empty. The canal was then opened, exposing the lower border of the conjoined tendons, and the sac dissected out. If the sac should be cut off at the level of the external ring and left in the canal or sewed up at any point below the internal ring, the remnant would invite a recurrence of the hernia. If twisting the sac were resorted to a portion of intestine might be injured. It was imperative that the sac should be opened, for there might be some omentum or intestine adherent within it. There was an additional advantage in being able to push the finger in and being sure that nothing but the sac was included in the ligature, which could then be applied just above the level of the internal ring. Some claim that if the conjoined tendon be brought against Poupart's ligament and sewed there it will unite with that ligament; but it cannot do so with any strength, for tissues so unlike in their structure can be made to unite only by first freshening their surfaces or by forcing them to granulate. Dr. McBurney does not allow the granulation tissue to form loosely in too wide a wound; for it is not intended that the cicatricial tissue itself shall support the abdominal pressure, but only that it shall firmly bind together the walls of the wound. To accomplish this the wound was harrowed by the use of tension sutures.

Case III.—The next case was a woman with a ventral hernia, the result of the yielding of the cicatrix left after some abdominal operation. The incision had been quite extensive, and the cicatrix was said to be three or four years old. The patient said that about three months ago, while making some unusual exertion, the swelling first appeared. The hernia was easily reducible, and as

it was covered with thin cicatricial tissue it threatened to enlarge rapidly. This case permitted entirely different treatment from the preceding; for these tissues could be incised and homologous structures brought together and made to heal by first intention. He thought it safer to cut down at either side of the hernia to avoid possible injury to adherent intestine. After some dissection the finger was introduced into the subperitoneal tissue. The operator said that it would be desirable to obliterate this loose pouch of peritoneum which had been in the sac, but as the intestine was evidently adherent such a procedure might involve injury to the gut. The tissues were united by a continuous catgut suture, layer by layer, the skin wound being brought together with silk. No drainage was needed. Healing by first intention and strong union should be obtained in three weeks.

CASE IV.—Dr. McBurney next exhibited a young man who had had a swelling in the left scrotum for eleven years. He stated that it had appeared suddenly after making some unusual exertion, and that it caused more or less discomfort. It became much larger a short time ago, after a sudden effort, but it had never been acutely inflamed. It had a peculiar feeling, not unlike that of a lipoma. There was the usual impulse on coughing noticed in varicoceles. The case resembled the kind of varicoceles sometimes seen in connection with abdominal tumors, but the patient had not been examined under ether with reference to this point. No abdominal tumor could now be found.

The subcutaneous method is excellent for small varicoceles; but for large ones Dr. McBurney prefers the open method. An incision was made from the external ring down into the scrotum. The case proved to be one of ordinary varicocele with much condensed areolar tissue which could not be dissected, as usual, by tearing, but required cutting with scissors. Apparently there had been considerable inflammation. The veins were separated from the cord and ligated at the external ring and again a short distance above the testis, and the portion included between these two ligatures excised. There were always enough healthy veins remaining to carry on the circulation. The two stumps were then stitched together with catgut, which brought the testis near the external ring, a position which would be permanent. The skin wound was closed with a continuous silk suture, and a drainage-tube inserted. An antiseptic dressing with rubber tissue and a spica bandage completed the operation.

MEDICAL PROGRESS.

A Successful Case of Inguinal Colotomy for Absence of Rectum in a Child Five Days Old.—DR. T. A. HELME, in the *British Medical Journal*, June 7, 1890, reports a case of this kind. He says: Complete obstruction of the bowels in the newborn child is not a very rare occurrence, and is dependent on one or other of a variety of pathological conditions. Most commonly the cause is found in the imperfect development of the lower bowel. It is a matter of importance, whenever the bowels of a newborn child do not move naturally, to make a careful examination for any gross lesion of the anus or rectum before proceding with purgative treatment; otherwise the only result may be aggravation of the child's suffering and hastening the commonly fatal issue. The history of the case related suggests the necessity of this precaution, and at the same time the successful result of the operative treatment adopted shows what may be hoped for from timely interference.

A male child, aged five days, came under observation on the evening of April 18, 1890, with the following history: The child was born on the evening of April 13th, when it presented every outward appearance of full and healthy development; the mother was a strong and healthy woman of twenty-six, and this was her first child. Two days later, April 15th, as the bowels had not yet moved, castor oil was administered. The desired effect not being brought about, the castor oil was repeated several times on the three succeeding days, and on the evening of April 18th, as the bowels still remained obdurate, the nurse was ordered to give the child a soap-water enema. As this could not be satisfactorily done, the child, presenting a most pitiable appearance, was brought to Dr. Helme. Its face was pinched and emaciated, its arms and body in constant movement, its legs repeatedly drawn up in a piteous manner on the abdomen, while it moaned continuously; evidently the child was in extreme pain. On examination, the abdomen was found to be greatly distended, the walls so thinned that the intestinal coils could be seen and their movements watched.

The perineal region presented a normal appearance, but on introducing the little finger into the anus the canal was found blocked by a membranous septum about half an inch from the skin surface. No bulging could be felt during the child's straining, from which it was evident that the lower end of the rectum was not in contact with the septum. Nevertheless, it was decided to puncture the membrane. No escape of intestinal contents following, Dr. Helme therefore carefully dilated the opening already made and introduced his finger into the peritoneal cavity. This examination confirmed his opinion; the rectum was altogether wanting, the blind bulging extremity of the sigmoid flexure being felt at the pelvic brim. Inguinal colotomy was, therefore, decided upon.

The operation, after washing the anal depression with weak sublimate solution, and introducing a strip of iodoform gauze, was done in the usual way on the left side. The abdominal wall was incised down to the peritoneum, the incision being about one inch and a half in length, parallel to the outer part of Poupart's ligament, and commencing externally a little above the anterior superior spine of the ilium. After compressing one or two bleeding points the peritoneal sac was carefully opened, when the bowel immediately presented in the wound. Two silk sutures were passed through the skin and parietal peritoneum of the one side of the incision (the muscular tissue being avoided), then through the bowel, the peritoneum and the skin of the other side. The bowel was then incised longitudinally for half an inch, the silk sutures were hooked up in a loop, divided, and tied on their respective sides; additional sutures were put in, completely closing the peritoneal sac. An immense quantity of material escaped from the bowel.

For several days after the operation there was con-

siderable redness encircling the wound, and some sloughing of cellular tissue around the adherent peritoneal surfaces. Gradually, however, this healed, the child, fed on peptonized milk, was discharged in an excellent state of health on the seventeenth day after operation. The mucous membrane had retracted within the bowel and the wound had healed perfectly. The sound introduced through the false anus passed in a downward direction for little more than half an inch, striking there the blind extremity of the colon.

This condition, complete development of the anus with absence of the rectum, is rare, and is likely to mislead the practitioner unless a very careful examination is made. Even on careful inspection the child appears to be perfectly developed, and unless the finger is passed into the anus the cause of the obstruction cannot be ascertained.

The history of this case of obstruction in the newborn child serves to emphasize the necessity of a careful digital examination of the bowel before resorting to any medicinal treatment. After the condition has been recognized the choice of operation seems to me a simple one. There are two alternatives, viz., inguinal or lumbar colotomy. But the three facts, namely (1) the small amount of space available; (2) the frequency with which one finds a long mesocolon in the infant, and the consequent displacement of the colon; (3) the relatively large size of the kidney and the consequent risk of injuring it, turn the balance in favor of opening the bowel in the groin.

On the Treatment of Metrorrhagia.—Dr. A. W. Edis, in the *Brit. Med. Journ.*, June 7, 1890, writes that in metrorrhagia a correct diagnosis being the first and most important element of treatment, it follows as a matter of course that having ascertained the presumed cause we know then what our plan of action should be. Still there are some practical hints which may be found to be of value to some. Where the hæmorrhage results from constitutional or general conditions it is not always wise to attempt to check the flow at once, unless it is producing such an effect upon the system as to suggest the expediency of arresting it at all hazards. In certain cases of heart disease uterine hæmorrhage, in place of aggravating, seems to relieve the cardiac symptoms, and should not, therefore, be hastily repressed. Strophanthus, digitalis, and aconite here prove most useful. Where the action of the liver seems to be at fault, attention to diet, abstention from alcohol, and the administration of a few grains of calomel, blue mass, or eunonymin, followed by a brisk saline aperient, will probably be indicated. If albuminuria be present, or if the kidneys seem to be at fault, encourage vicarious action of skin and bowels by means of diaphoretics and purgatives, and follow out any other indications suggested. In cases of menorrhagic chlorosis, bromide of potassium in half-drachm doses has proved of service, iron with strychnine being given between the periods and attention being also given to ordinary hygienic details, to avoidance of tight lacing and of physical overwork. It is well to remember that hæmophilia, scurvy, malaria from residence in damp or marshy districts, lead-poisoning, and other unusual conditions will occasionally explain the presence of metrorrhagia. The mere recognition of the cause will be at once a suggestion as to the proper course of treatment.

Where uterine hæmorrhage persists, notwithstanding the employment of constitutional measures, and there is no apparent local cause to account for it, we should without further delay dilate the cervix uteri and explore the interior of the uterus. Numerous instances have been recorded of patients dying from uncontrollable hæmorrhage, where a *post-mortem* examination revealed the existence of some intra-uterine growth, such as a polypus or submucous fibroid, retained product of conception, or fungoid condition of the endometrium, which could readily have been removed or dealt with had appropriate measures been adopted in time.

The insertion of a sponge tent into the cervix uteri arrests the hæmorrhage for the time being, and facilitates subsequent exploration of the uterine cavity. As to any risk of reflux through the Fallopian tube, as sometimes spoken of, it is a mere visionary objection, and need not deter us from employing dilatation in suitable cases. Plugging the vagina is a very unscientific procedure, as well as being unsatisfactory and inefficient. It should seldom, if ever, be resorted to.

It would clearly be impossible in these brief remarks to indicate in detail the methods of local treatment, such as curetting for villous endometritis, removing polypi, operating for cancer, the use of electricity in cases of myoma, the best method of dealing with cases of incomplete abortion, or replacing an inverted uterus. If we have once clearly made out the indications for treatment the remainder is merely a matter of detail. But now and again instances occur where no assignable cause, either constitutional or local, can be made out, and where remedies fail to restrain the hæmorrhage In such cases the hot vaginal douche may prove of service, or even washing out the uterine cavity with hot water through a double-current catheter, provided the cervix be patulous enough to admit it. Should this fail it may be considered requisite to wash out the interior of the uterus with a strong solution of iodine or of iron. As a *dernier ressort*, the insertion of a sponge tent into the cervix uteri may be effected.

The reliable remedies at our disposal for checking or arresting uterine hæmorrhage are really very few. Ergot is unquestionably one of the most potent; Hydrastis Canadensis is a valuable agent and far too little generally known. In cases of myoma it often proves of service when ergot has failed. Hamamelis, which forms the basis of the American nostrum hazeline, is sometimes useful. Quinine and strychnine, alone or in combination, often succeed in checking or arresting hæmorrhage in those cases where the system is much depressed from repeated or prolonged losses. Bromide of potassium in cases of ovarian irritation, and even in hæmatocele, possesses thd power of checking hæmorrhage and is equal, if not superior, to any remedy we possess. Chlorate of potassium in combination with ergot has lately been strongly recommended. Opium is beneficial in cases where the loss has already been severe. Sulphuric acid and opium formerly were, and still are, with some practitioners, favorite remedies; also, acetate of lead and opium in the form of pill.

The ordinary astringents, such as gallic and sulphuric acids, have really very little influence in restraining

hæmorrhage, and are far too often relied upon. Iron is often of much benefit in those cases where the loss has been very profuse, as in myomata, and where the blood has become so attenuated as to pass readily through the capillaries. Digitalis, in combination with iron, proves most valuable in cardiac complications.

In place, however, of attempting to deal empirically with the effect, we should always endeavor to arrive at a definite opinion as to the cause of the hæmorrhage, and, if we can deal with this satisfactorily, the treatment is very simple.

Prescription for Impetigo Contagiosa.—Saalfeld recommends the following somewhat elaborate ointment in the treatment of impetigo contagiosa (*Medicinische-chirurgische Rundschau*):

R.—Potassium carbonate		1 part.
Olive oil		10 parts.
Zinc oxide, Starch	of each	15 "
Salol		5 "
Sulphur		6 "
Lanolin		100 " —M.

Local Application for Diphtheria.—This formula, to be used as a local application in the treatment of diphtheria, is quoted in the *Medicinische-chirurgische Rundschau*:

R.—Carbolic acid	1¼ to 2½ drachms.
Camphor	5 to 7½ "
Tartaric acid	4 to 10 grains.
Olive oil	9 to 12 drachms.
Alcohol	2½ "

To be applied with a soft brush.

Tiersch's Method of Skin-grafting.—In a thoroughly practical paper upon skin-grafting, Mr. W. Watson Cheyne gives the following advice upon the methods to be employed (*Practitioner*, June, 1890):

1. The proper time for grafting is when cicatrization is distinctly advancing at the borders of the wound. If we wait much longer than this an unnecessary amount of granulation tissue will form, and the contraction of the scar will be excessive.

2. Before attempting to graft, the surface of the ulcer should be aseptic; if it is not, suppuration between the granulations and the graft will prevent union. Asepsis of the sore is best secured by washing the surrounding skin with carbolic and sublimate solutions, mopping the ulcer with zinc chloride solution (40 grains to the ounce), then dusting it with iodoform, and dressing with borated lint which has been dipped in a 1-to-2000 sublimate solution. Excepting the zinc chloride, this treatment should be repeated for several days before applying the grafts.

3. Just before grafting, the superficial layer of the ulcer should be shaved or scraped off, checking hæmorrhage by the pressure of a sponge under which is a piece of protective.

4. While the bleeding is being arrested the grafts should be taken, preferably from the thin skin of the flexor surface of the forearm. The skin which is to be used should be shaved and disinfected by scrubbing with a 1-to-500 sublimate solution, then with a 1-to-20 carbolic solution. A strip of skin about one inch wide and as long as desired is then dissected off, avoiding the subcutaneous tissue. The strip is cut into pieces about half an inch long, and planted on the prepared surface. The grafts should be numerous and nearly touching one another. It must be remembered that they shrink considerably.

5. When the operation is completed, the surface is covered with protective, and gentle pressure is made to squeeze out any blood that may be between the grafts and the surface of the ulcer. The remainder of the dressing is boric lint, salicylated cotton, and a bandage. The dressing may be renewed on the third day.

The Preparation of Beef Juice.—According to the *Dietetic Gazette*, the following is the proper method of extracting the juice from beef: Broil half a pound of beef for a moment over a hot fire, then score it thoroughly, and with a lemon-squeezer press out the juice. Add a pinch of salt, and warm before administering.

Formula for the Hypodermic Administration of Ergotinin.—Baroni uses the following formula for the hypodermic administration of ergotinin:

R.—Ergotinin, Lactic acid	of each	3 grains.
Cherry-laurel water		5 drachms.
Distilled water		3 ounces.—M.

The dose of this is from fourteen to eighteen drops.—*Gazette de Gynécologie*, June 1, 1890.

An Antiseptic for Midwives.—The Paris correspondent of the *Pharmaceutical Era* writes that the Academy of Medicine has formulated the following antiseptic powder to be dispensed to midwives, upon their order in writing:

Corrosive sublimate,	3.8 grs.
Tartaric acid,	15.4 "
Five per cent. solution of indigo-carmine,	1 drop.

Mix and dry.

Each powder to be dissolved in one quart of water, must bear the regulation orange-red label, with the words "Corrosive Sublimate. Poison."

Iodine in the Treatment of Retinal Detachments.—In the Berlin Medical Society, on May 7th, Schoeler made a further report on the use of intra-ocular injections of iodine in the treatment of retinal detachment. A total of twenty-eight cases had been so treated, and details were given as to the five successful and the remaining more or less successful cases—three of the latter being really nearly complete successes. A number of the cases had been desperate, and hardly suitable, from their long duration, the presence of cataract, etc. Serious hæmorrhage ruined the result in three eyes; minor extravasations lessened it in two cases; and in five a brilliant success proved but transient. Based upon a series of studies upon animals, and already attended with some success, the method seems worthy of fuller study, especially by laboratory experiments; and while an expectant treatment by rest, etc., should always be tried first, there is great likelihood that the method can be used in otherwise hopeless cases with moderate safety and considerable hope of cure.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE TREATMENT OF TUBERCULOSIS IN SANITARIA.

GERMAIN-SÉE, with the collaboration of M. JOURMON, discusses in *La Médecine Moderne* (May 15, 1890, No. 21) the utility of special hospitals for the treatment of phthisical patients of moderate means. This is a subject of very great importance, and the attitude of the profession is constantly becoming more and more favorable to the method.

There are many reasons why this should be so. In the first place, it is much more generally recognized that pulmonary phthisis is an affection in the treatment of which mere drug-giving is utterly useless: and measures designed to promote nutrition, as well as special therapeutic means directed against various incidents of the disease, must be faithfully, assiduously, persistently, and hopefully applied in order to be effective.

The average practitioner has not the familiarity with these measures, the hopefulness or the facilities necessary to carry them out in the proper manner. Hence, institutions, with their corps of trained physicians, experienced nurses, specially instructed cooks, their inhalatoriums, baths, sun-parlors, parks, and other desiderata, occupy a vantage-ground in the struggle against this disease immeasurably superior to that which can ordinarily be gained in the homes of any but the most wealthy patients; while some of the advantages of certain institutions cannot be obtained even by the greatest wealth.

Sée and Jourmon advance the following arguments:

In the first place, they claim that the treatment of tuberculosis may be reduced to two terms: first, the hygienic management of the patient; and second, prophylaxis.

They admit that all endeavors to find a parasiticide which would destroy the bacillus tuberculosis and allow the patient to live, have proved futile. Creasote is the only medicament which has retained the slightest credit in this direction, and it is extremely doubtful whether even this has any direct influence whatever upon the life of the microbe. When it has a good effect, this is to be attributed to the favorable influence which it exercises upon the character of the secretions. The problem, therefore, is reduced to the best means of rendering the tissues invulnerable; in other words, to bring about a "normal sterilization." The experience of the most competent observers in all countries shows that measures directed toward conserving and improving the nutrition of the patient, and varying with the idiosyncrasies of the individual, are the only means of accomplishing this. For the vast majority of patients these means are not attainable except in hospitals.

In the second place, the recognition of the specific nature of the disease, especially when one takes into consideration the great number of persons affected, makes it evidently injudicious to place them in general hospitals; even were it practicable there to devote to them the special attention which the peculiar nature of the treatment demands.

A further advantage in the establishment of special institutions is the fact that their location can be selected with due regard to climatic influences; and that all the details of internal arrangement and of surroundings, can be so managed as to reduce to a minimum the disadvantages of civilization, while retaining its comforts.

If typhoid fever alone can be excluded, and there is no reason why it should not be, from among the dangers to which the person of phthisical tendencies is exposed, there will be a great gain. The authors admit that it is vexatious and unnecesary to insist on the sequestration of phthisical patients as a measure of public health, on the ground of the supposed contagiousness of the disease. With proper precau-

tions all danger of its spread from person to person can be obviated.

In discussing this subject all honor and credit must be paid to the late Dr. Hermann Brehmer, who, in 1855, established his sanitarium at Goerbersdorf, in the face of much opposition, winning a success which has led to the multiplication of similar institutions in Germany and elsewhere. The institution at Goerbersdorf, with its accretions of thirty-five years, remains the model to which we must still turn for instruction as to the best means of securing the objects in view. It is now conducted by the assistants of Brehmer and by his widow.

A beginning has been made in this country, and the sympathy and interest of the profession should be sufficiently aroused to induce them to lend every encouragement to make the attempt successful.

It is not of charitable institutions that we are now speaking, it must be remembered, but of resorts for persons of moderate means, who can afford to pay for their board and care, but who cannot afford to pay for the skilled nursing and therapeutical appliances necessary to successful treatment, when the entire cost of these must be defrayed from individual resources. In special institutions, this expense being divided among many does not bear too hardly upon any one. We hope that some practical philanthropist will be induced to found such a sanitarium in the neighborhood of Philadelphia. If it merely accustoms the profession in this vicinity to a hopeful view of the resources of intelligent therapeutics, it will do much to save the lives even of patients beyond its walls.

THE RADICAL CURE OF CANCER OF THE CERVIX UTERI.

On this important and interesting topic two opinions stand in opposition at the present day. Some operators regard vaginal extirpation of the uterus as offering an excellent prospect for recovery. Others limit their operations to ablation of the cervix with cauterization of infiltrated tissues, regarding the disease as incurable, and seeking in this way to prolong the patient's life and to relieve her sufferings. In his studies upon the catheterization of the ureters, Pawlik (*Archives de Tocologie*, May, 1890) observed that cancer of the cervix usually spreads laterally before involving the body of the uterus. He also found that the ureters were rarely involved in this infiltration, and that it would be possible to extirpate the pelvic tissue with the uterus without injuring the ureters. Accordingly, in four cases of cancer of the cervix, he inserted a catheter into the ureters and extirpated the connective tissue of the pelvis with the affected organ. His results justified the inference which he drew from his observations. So far as a recurrence is concerned—only one of his patients could not be heard from subsequently—two of the women were in good health without recurrence over a year after operation; the fourth had cystitis with uretero-vaginal fistula. An operation to close this was refused, but the patient's general health continued good.

While the number of cases is too small to base a definite conclusion upon, yet it seems rational to follow Pawlik's suggestion. The catheterization of the ureters, however, while not exceedingly difficult, requires constant practice. We remember very well the skill with which Professor Pawlik illustrates and performs this little manipulation, and under his eye we have successfully followed his example: but when we remember that he embraces every opportunity to practise the exploration of the ureters, and that he finds constant practice requisite to maintain his remarkable dexterity, it is evident that the average operator may have difficulty in following his example. Without a guide in the ureter, it would certainly be unsafe to attempt the extirpation of the peri-uterine connective tissue, and also it would be impossible to tell whether malignant infiltration had not attacked these important channels. In the hands of an operator as skilful as Pawlik the method should certainly receive fair trial, but those less experienced and skilful should attempt it with caution. It is applicable to cases in which the pelvic connective tissue is only partially affected, in which the uterus is movable, and in which the fundus remains intact.

REVIEWS.

Practical Electricity in Medicine and Surgery. By G. A. Liebig, Jr., Ph.D., and George H. Rohé, M.D. Philadelphia and London: F. A. Davis, 1890.

This book having the stamp of Johns Hopkins University upon its title-page at once excites the expectations of the reader. The first part is devoted to a careful consideration of the various forms of the electrical and magnetic apparatus commonly used in medicine, together with the theory of the chemical actions taking place in the storage cell, a description of the electric motor, and the telephone and the phonograph. Though in this part of the book one is somewhat appalled by weird spiral figures, and pages of algebraic formulæ, it must be ad-

mitted that a student who has already acquired a thorough knowledge of mathematics and is well grounded in physics will have little difficulty in catching the drift of the subject-matter. To those not so thoroughly prepared an omission of this portion of the work will be found, perhaps, as useful as a careful perusal, and will, moreover, be less confusing.

Part second is devoted to electro-physiology, electro-diagnosis, and electro-medical apparatus. Into this subject the authors have dipped with great thoroughness, and though their descriptions are not always clear, they are invariably comprehensive. The sins of omission are few. In the chapter upon special electro-therapeutics specific directions are given for the electrical treatment of each disease. Thus, insomnia is treated by galvanization of the brain and medulla, general faradization, subaural and spinal galvanization, and static electricity. These concise yet comprehensive suggestions will, we think, be found of great service to the general country practitioner. Enlargement of the spleen, ascites, diabetes mellitus, and many other conditions are, it is claimed, benefited or cured by the electrical treatment.

We would say, in general, that this book suggests a compilation rather than the result of ripe experience, and that, like all other works constructed on this plan, it has not given the profession exactly what is needed.

PRACTICAL PHOTO-MICROGRAPHY, BY THE LATEST METHODS. By ANDREW PRINGLE, F.R.M.S. New York: The Scovill & Adams Co., 1890.

NOTWITHSTANDING that the book before us, as we are told by the author, was "written deliberately and confessedly for the natural and medical sciences rather than for those who use the microscope as a pastime," American workers in these fields will feel that their needs have been but partially appreciated. What the investigator wants is the simplest possible method of arriving at thoroughly satisfactory results.

Illumination—that matter of the greatest importance for successful photo-micrography—is very inadequately discussed. While admitting that sunlight is, perhaps, the best of all illuminating agents, the author confesses that he has had but little experience with this illuminant, and, therefore, allows the unfortunate condition of British skies so to warp his judgment, that he gives utterance to the regret that those older notably successful cultivators of photo-micrography—Woodward among others—had not the advantages of "equable radiants and very sensitive plates." Does the author imagine that Dr. Woodward continued to use sunlight because the capabilities of the electric, magnesium, or lime-light were unknown to him? While Woodward's experiments showed that these were useful and fairly satisfactory substitutes for sunlight, he, as well as every experienced worker who has made comparison since, clearly recognized the great superiority of sunlight over all other sources of illumination. Let every one who seriously desires to produce the highest class of work, determine, from the start, to use sunlight, regarding the proper management of which, however, he will find little in the present volume.

Having expressed our dissent from what we are convinced is mistaken advice, it is a pleasure to endorse heartily the author's high estimate of the value of color-screens and of the apochromatic objectives. The examples of work serving as illustrations are very creditable, especially so when it is remembered that all were taken by artificial light—this, with one exception, being the lime-light. The confusion arising from printing the figures of Plate IV. over the descriptions of Plate V., and *vice versâ*, possibly extends to only a small part of the edition. Debarring the opinions already discussed, and a few slight inaccuracies, there is an abundance of hints valuable to all interested in photo-micrography.

CORRESPONDENCE.

NEPHRITIS FOLLOWING INFLUENZA.

To the Editor of THE MEDICAL NEWS.

SIR: In *The Lancet* of May 10th, Dr. E. Mansel Sympson describes a case of acute nephritis following influenza, and I have a similar case to report, as well as four cases to mention, in which disease of the kidneys became prominent after attacks of "La Grippe."

CASE I.—Patrick D., private of Marines, aged twenty-five years, a native of Ireland, was admitted to the United States Naval Hospital, Washington, on February 25, 1890, with catarrhal fever, which began on the day before with severe muscular pains, nausea, anorexia, a temperature of 103° F., and a pulse of 90 per minute. About this time the epidemic of influenza was nearing its end here. The patient had also been treated for gonorrhœa from February 11, 1890.

On his arrival at the hospital he was very restless, complained of frontal headache, and of pain in the muscles of his back and in the calves of his legs; his eyes were red and watery; nausea, bilious vomiting, and looseness of the bowels were present, with a temperature of 101° at 2 P.M., rising to 101.4° at 6 P.M., and a pulse of 100. Lungs and heart normal; no cough or expectoration. Quinine was given, but otherwise the treatment was expectant.

26th. No better; temperature 102.6°; nausea and vomiting continue.

27th. Much worse; pulse 96, temperature 102°; is very restless; complains of almost constant nausea and uneasiness in the stomach. At 5 P.M., pulse 100, temperature 99.4°; somewhat better.

28th. Rested well last night after a dose of chloral and potassium bromide; temperature 99.2° in the morning, and 101.2° at 5 P.M.

March 1. Temperature 98.4° at 8 A.M., rising to 100.6° at the evening examination. Improving; discontinued medicines.

2d. Temperature normal.

5th. Is up and about the ward. Ordered the following injection for his gonorrhœal discharge: Sulphate of zinc and acetate of lead, of each 4 grains; distilled water 2 ounces.

9th. Discharge from the penis has almost stopped; at 8 P.M. he went to bed with a chill, which was followed by a rise in temperature.

10th. Is better; the urethral injection continued.

11th. Much worse; had a chill during the night, followed by a temperature of 103.2°.

12th. Somewhat better; temperature 101.2° in the morning, and 101.6° at 4 P.M.; complained of uneasy

sensations in his stomach and pain in the back; discharge from the urethra had ceased.

13th. Temperature normal in the morning, but rose to 102° in the evening; discharge from the urethra returned.

14th. Temperature normal in the morning, rising to 100 4° in the evening; complained of nausea and uneasiness in the stomach, and of great pain in the right lumbar region; tongue much coated.

15th. Not so well; temperature 100°, rising to 104° in the evening.

16th. Temperature 100°, rising to 103° in the evening.

17th. Urine this morning contained blood, pus, and some *casts;* it is also highly *albuminous;* temperature 101°, rising to 103° in the evening; complained of pain over the right kidney.

18th. Better; temperature normal in the morning, but rose to 100° in the afternoon.

20th. Much better; temperature normal.

24th. Urine still cloudy, contains blood and pus-corpuscles, but the patient is improving.

31st. Urine clearing up; still of low specific gravity and pale.

April 3. Urine pale, specific gravity 1011; contains a little blood and mucus, but no casts.

13th. Urine clearing up; specific gravity 1016; patient much better.

22d. Patient restored to health, and discharged to duty.

As with Dr. Sympson's case, a complication exists in mine. His patient had ancestors who suffered from renal calculus and gravel; and the doctor suspects "hereditary weakness or predisposition" to renal disease. My patient had gonorrhœa, which was treated with copaiba before he came to the hospital, and with a fairly strong urethral injection here.

These two cases resemble many others in which "la grippe" seems to have found a nidus for its redundant germs to work mischief in organs already enfeebled by other causes.

For a time I was in doubt about the cause of nephritis in the case I have reported, attributing it to an extension of the gonorrhœal inflammation to the right kidney, which had been the seat of acute pain; but Dr. Sympson's case, together with some others which I will mention, leads me to believe that influenza was at least one of the chief exciting causes of the nephritis.

Case II.—A patient died with uræmia at this hospital on January 24, 1890. He had suffered with influenza on January 5th, and was sent here for acute pleuritis on the 9th of the month. Autopsy revealed recent adhesions on both sides, but more on the left side. He had a urinary fistula at the root of his penis, resulting from a urethral stricture; his urine had only dribbled away for several years. There was hydronephrosis on each side. The left kidney weighed four ounces, its cortical portion having almost entirely disappeared; its pelvis and calyces were dilated. The right kidney weighed seven and a quarter ounces, its cortical portion having undergone some degeneration also from the existing hydronephrosis. The Malpighian bodies were small and indistinct; pelvis and ureter very much dilated, and discharging a dirty, brownish-looking liquid when cut open.

Case III.—On February 28, 1890, a lieutenant in the U. S. Navy was admitted to this hospital with albuminuria; the hospital ticket stated as follows: "Albumin first noticed in urine following an attack of epidemic influenza in the latter part of December, 1889, and the beginning of January, 1890, at U. S. Naval Training Station at Newport, Rhode Island. A very few hyaline casts were found, and albumin to the extent of about ¼ of one per cent. persisting, with symptoms of lung irritation, cough, cold extremities, etc."

The patient has the lithæmic diathesis, and is subject to rheumatoid pains, and a slight swelling of the feet.

On March 16th the examination of his urine showed a very faint trace of albumin, very few hyaline and granular casts, a specific gravity of 1016, and an acid reaction. He felt stronger, and on going out into the city he came back less fatigued than on other days recently.

On May 2d he was detached from this hospital and placed on sick-leave, his urine still showing albumin and casts.

On May 17th I had a letter from him dated two days earlier, in which he stated that he had not kept up the modified milk-diet on which I had placed him, that he did not feel so well, and had more albumin in his urine than he had while here.

Case IV.—On March 5, 1890, a patient was admitted to this hospital with pneumonia of the right lung. His hospital ticket described him as having been ailing for ten days before he was received here. His case resembled the numerous cases of pneumonia that followed "la grippe" in this vicinity about the same period. As he came from a tender that had no medical officer on board, he was not examined until pneumonia had set in, and this fact renders it probable that his preceding ailment was due to the then prevailing epidemic of influenza. His sputum was very much tinged with bile, he was intensely jaundiced, and for weeks after his convalescence from pneumonia his urine looked like brown-stout.

The most interesting point in this case is that, about the beginning of May, 1890, his urine was found to have a very low specific gravity, though albumin has never been found in it. On May 6th the record reads: "Urine clear, but of low specific gravity (1005)." In other respects he was quite comfortable, and on May 22d he was discharged to do duty as a servant. His conjunctivæ were still a little yellow; his skin did not reveal anything, as he is a negro; and his urine was normal in appearance. Could the influenza germs have irritated both liver and kidneys, as well as the right lung, in this case?

For the notes relating to the foregoing cases, and for the examinations of the urine, and the necropsy in the fatal case, I am indebted to Dr. D. O. Lewis, U. S. Navy, the resident medical officer of this hospital.

Case V.—Another case bearing upon this subject has come to my knowledge. A friend and fellow medical officer recently died of pneumonia following an attack of influenza, during the height of the epidemic at Mare Island, California; he had suppression of urine before death, and at the necropsy he was found to have the "large white kidneys of Bright," in fact they were said to have been double the normal size.

While the five cases reported by me do not prove that

the germ of "la grippe" alone caused the renal complications, yet I believe they do show that an attack of influenza often brings to the patient's notice the existence of serious or even fatal kidney disease previously unsuspected.

A. A. HOEHLING, M.D.,
Medical Inspector, U. S. N., in charge.

WASHINGTON, D. C.

NEW YORK.

To the Editor of THE MEDICAL NEWS,

SIR: The busy round of society meetings, lectures and clinics has given place to the usual lethargy of the heated term, and medical men are more interested just now in planning for a short season of recreation than in medical matters. Those less fortunate ones, who are compelled to remain in the city all summer, are either dazed at the prospect, or, making the best of their lot, have begun their annual struggle with the problem of summer diarrhœa, and are endeavoring to determine the best methods of infant feeding.

New York has not had to wait this year until the "dog days" to record a case of hydrophobia; for a genuine case of this much dreaded disease was brought to Bellevue Hospital the other day. The patient was a middle-aged man, bitten by a dog several weeks previously. He was brought to this city for the purpose of receiving the Pasteur treatment; but he arrived too late for this to be of any avail. Dr. Paul Gibier, who has treated at his institute here about thirty-five cases since last February, says that inoculations made after the appearance of the symptoms of hydrophobia are useless; although he has successfully treated one patient who had already begun to complain of tingling at the seat of the bite, which had been received about six weeks before. I understand that a sufficient donation has been offered Dr. Gibier to enable him to erect a properly equipped Pasteur Institute. The most recent statistics of this mode of treatment lead him to believe that the mortality may be reduced to absolutely nothing.

The ex-internes of our hospitals seem to have suddenly awakened to the advantages of forming themselves into associations, and this spring has witnessed the organization of two such—*i. e.*, the Alumni Association of Charity Hospital and that of the Mount Sinai Hospital. It is to be hoped that they will strive to equal the admirable record already made by the Bellevue Alumni. At a recent meeting of the latter Society, Professor A. L. Loomis discussed the relations of digitalis to cardiac disease. He believes digitalis to be the most reliable of all the so-called heart tonics; but that it requires exceptional skill and judgment to administer it efficiently. It should never be given so long as the compensatory hypertrophy is sufficient to maintain a good general circulation; but when the first signs of irregularity and failing strength are discernible, after careful and repeated examination, the drug should not be longer withheld. It is, he thinks, a mistake to give it in large doses, except in emergencies; and when the case seems to demand doses of more than five or ten drops of the tincture, he makes it a rule to insist upon the patient remaining in the recumbent position. A neglect of this precaution not infrequently leads to sudden and fatal syncope. His guide in the administration of digitalis is the quantity of urine excreted. If the quantity increases while the patient is taking the digitalis, the remedy is doing good; but if the quantity remains small or diminished it is an indication that the drug is not accomplishing the desired object. Where he wishes a tonic effect, he prescribes the tincture; but where large doses are required in cases of advanced cardiac insufficiency, or where it is desirable to produce diuresis, he prefers the infusion. Several of the members spoke of the large doses of digitalis that are sometimes tolerated, and Dr. Van Santvoord said that he knew of a case of pneumonia under the care of a homœopathic practitioner, where the tincture of digitalis had been administered in teaspoonful doses, the patient experiencing no disagreeable effects. Such a case as this is interesting, both on account of the tolerance exhibited by the patient and the disregard of the doctrine of infinitesimals displayed by this disciple of Hahnemann. Certainly, if this practitioner is a worthy representative of his clan, the homœopaths of this degenerate age need have no fears concerning the effect of the tariff reform upon the price of milk-sugar.

At the last meeting of the New York Academy of Medicine, Dr. George M. Sternberg briefly described some of his bacteriological researches in yellow fever, and exhibited a series of lantern slides showing photographic representations of many of the organisms which he has studied in connection with the subject. He said that when one considers the mode of distribution of the disease, and the great success which has attended the treatment of it simply by sanitary measures, it is difficult to resist the conclusion that yellow fever is due to a particular germ, which probably finds a favorable nidus in the fæces. Notwithstanding the fact that he undertook his researches with the full expectation of finding such a germ, no characteristic organism has been as yet discovered. It is interesting to note that throughout his investigations he has never met with anything resembling the cholera bacillus.

At the close of Dr. Sternberg's remarks, the President, Dr. Loomis, reminded the Fellows of the Academy that this was the last meeting to be held in the old building, which has been the home of the Academy for nearly twenty years. During this time its membership has nearly doubled, and these years represent an important epoch in its history; for it was during this time that the sections had come into life. It has been estimated that the collective work of the Academy is greater than the total of all the other medical societies in the State. It is true, he said, that the present building has been the scene of some pretty active skirmishes, both scientific and ethical, but he hoped that all petty jealousies would be left behind in the old building, and that the Fellows would enter their new home with the determination to do better scientific work, and to promote that sociability among the members which is the best prophylactic for those bickerings and petty squabbles, which too often interfere with the proper unity of the profession.

NEWS ITEMS.

The Pasteurian Institute in New York.—The work of Dr. Paul Gibier, in the prevention of hydrophobia, is constantly increasing, and he inoculates about twenty persons daily. The quarters in which his work was begun about four months ago have been outgrown, and a

removal to a larger permanent building must be made very soon. Already there have been offers of valuable property made to Dr. Gibier by citizens interested in promoting his work. One offer, that of a large dwelling surrounded by spacious grounds, and not far from Central Park, has many suitable features, and will probably become the future home of the Institute. It is stated that during the current summer Dr. Gibier will visit Europe, and that his place will be temporarily filled by one of Pasteur's principal assistants who will come to this country for the purpose.

The Italian Sanitary Council and the Sale of Nostrums.—The *British Medical Journal*, May 24, refers to the consequences in Italy of certain new laws for the suppression of the sale of patent medicines and other "specialties." The article says "the golden age of nostrums in Italy is past and the iron age has begun. No proprietary nostrums may now be offered for sale in that country unless they are favorably passed upon by the Superior Sanitary Council. Over 200 such articles have been rejected, and at a meeting on May 13th every article then before the Council was disallowed, and the grounds of this action were made public, namely, that all these rejected 'specialties' contained remedies which cannot be used with safety except under the direction of a medical man; that many of the articles were actually dangerous, and that many others possessed none of the virtues attributed to them."

The Origin of Hospitals.—In the *Lancet*, May 31, is an archæological summary of the most recent discoveries and researches regarding primitive institutions for the care and cure of the sick and wounded. Hospitals existed in India as early as the fifth century, B. C. In Ceylon, according to the English Orientalist, Turnour, King Pandukabhayo, established a hospital in his palace, and one of his successors, King Dutthagamini, in the second century before Christ, established eighteen such institutions in as many different localities, with a medical staff for each, and the remedial agents of those days. The Buddhist King, Asoka, as shown by Dr. Bühler, had, about the year 250 B. C., hospitals both for man and animals. There were doubtless many other founders of hospitals whose names are lost, but the *Lancet* thinks that their work was less important than that of the hospitals which developed in Rome and elsewhere as the result of the spread of Christianity.

Beaumont Hospital Medical College.—According to the *St. Louis Courier of Medicine* the corner-stone of the Beaumont Hospital Medical College, laid on May 31st, contained a copy of Lawson Tait's *Diseases of Women and Abdominal Surgery*, presented for the purpose by the author.

A Relief Fund for Dr. J. H. Douglas.—Dr. T. Gaillard Thomas has written to the *New York Medical Journal* a letter in which a plea is made on behalf of a physician who is ill and in want, Dr. J. H. Douglas, best known as the physician of General Grant, in his last illness. Dr. Douglas is now an inmate of the Presbyterian Hospital, of New York. Dr. Willard Parker may be addressed by those desiring to co-operate in the raising of a fund for the relief of their afflicted *confrère*.

American Otological Society.—The twenty-third annual meeting of the American Otological Society will be held on Tuesday, July 15th, at the Hotel Kaaterskill, Catskill Mountains. Papers will be read by Drs. C. H. Burnett, A. H. Buck, B. Alexander Randall, F. M. Wilson, Huntington Richards, S. Theobald, Charles A. Todd, O. D. Pomeroy and Lucien Howe.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 1 TO JULY 7, 1890.

GARDINER, JOHN DE B. W., *Captain and Assistant Surgeon.*—Having been found incapacitated for active service by an Army Retiring Board, and having complied with Par. 12, S. O. 135, June 10, 1890, from this office, is, by direction of the Acting Secretary of War, granted leave of absence until further orders, on account of disability.—Par. 3, *S. O. 153, A. G. O., Washington, D. C.*, July 2, 1890.

ROBINSON, SAMUEL Q., *Captain and Assistant Surgeon.*—Is relieved from temporary duty at the U. S. Military Academy, West Point, New York, to take effect upon the arrival there of W. Fitzhugh Carter, Captain and Assistant Surgeon, and will report in person to the commanding officer Fort Du Chesne, Utah Territory, for duty, relieving Curtis E. Price, Captain and Assistant Surgeon. Captain Price, on being relieved by Captain Robinson, will proceed to Fort Wadsworth, New York Harbor, and report in person to the commanding officer of that post for duty, relieving Robert B. Benham, Captain and Assistant Surgeon. Captain Benham, on being thus relieved from temporary duty at Fort Wadsworth, will report in person, without delay, to the commanding officer Fort Hamilton, New York Harbor, for duty.—Par. 12, *S. O. 153, A. G. O., Washington, D. C.*, July 2, 1890.

By direction of the Acting Secretary of War, leave of absence for four months is granted JAMES P. KIMBALL, *Major and Surgeon*, to take effect when an officer of the Medical Department is assigned by his department commander to relieve him.—Par. 6, *S. O. 152, A. G. O., Washington, D. C.*, July 1, 1890.

By direction of the Secretary of War, the following named Assistant Surgeons (recently appointed, with the rank of First Lieutenant) will report in person to the commanding officers of the posts designated opposite their respective names:

KEEFER, FRANK R., Fort Leavenworth, Kansas.
RAYMOND, THOMAS U., Fort Sherman, Idaho.
SNYDER, HENRY D., Fort Reno, Indian Territory.
SMITH, ALLEN M., Fort Snelling, Minnesota.
HEYL, ASHTON B., Fort Niobrara, Nebraska Territory.
CLARKE, JOSEPH T., Fort Riley, Kansas.—Par. 6, *S. O. 151, A. G. O., Washington, D. C.*, June 28, 1890.

CORBUSIER, WILLIAM H., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Lewis, Colorado, and will report in person to the commanding officer Fort Wayne, Michigan, for duty.—Par. 7, *S. O. 151, A. G. O., Washington, D. C.*, June 28, 1890.

BALL, ROBERT R., *First Lieutenant and Assistant Surgeon.*—Is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer Fort Spokane, Wash., for duty.—Par. 7, *S. O. 151, A. G. O., Washington, D. C.*, June 28, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING JULY 5, 1890.

PAGE, JOHN E., *Assistant Surgeon.*—Ordered to Hospital, Mare Island, California.

KENNEDY, ROBERT M., *Assistant Surgeon.*—Ordered to the League Island Navy Yard, Pennsylvania.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

LEUKÆMIA AND PREGNANCY.[1]

With Report of a Case.

BY W. W. JAGGARD, M.D.,

PROFESSOR OF OBSTETRICS IN THE CHICAGO MEDICAL COLLEGE, AND OBSTETRICIAN TO MERCY HOSPITAL, CHICAGO.

THE purpose of this communication is to place on record an example of fatal lienal leukæmia, that seems to have sustained some necessary relation to pregnancy, or to prolonged lactation during pregnancy, or to both these factors.

The notion of some necessary relation between the female generative organs and leukæmia has long been accepted. Thus Virchow,[2] the discoverer of leukæmia, writes on the etiology of the disease:

"The only thing that can be asserted with any degree of certainty is the connection with the sexual functions in woman."

And Mosler[3] says:

"Disturbances of the sexual functions in woman have an influence in the origin of leukæmia that is unmistakable. There exists a certain connection between the female genital organs and spleen. An acute splenic tumor with slight increase of the white blood-corpuscles often arises in consequence of anomalies of menstruation."

Within a recent period, however, the nature of the evidence upon which this notion rests has been called in question by Sänger,[4] in an excellent critical review of the literature of the subject. This testimony, he writes, is not the language of modern gynecology.[5]

"The question, up to the present surrendered entirely to internal medicine, must be investigated anew by gynecologists, who hitherto have interested themselves in leukæmia and splenic tumors only in their relation to differential diagnosis for the purpose of laparotomy."

It is a fact that leukæmia occurs twice in men to once in women. Among 91 cases Ehrlich found 60 males and 31 females, while among 201 cases Birch-Hirschfeld found 135 males and 66 females. This unequal occurrence exists in spite of, or perhaps on account of, the greater demands on the blood-glandular system of women. Now, if menstrual disturbance, so commonly observed, were always of primary, causal moment, the world would swarm with leukæmics. On the other hand, does it not seem probable that the more active blood-metabolism is the factor that tends to shield the female sex from leukæmia?

On the reciprocal relations of leukæmia and menstruation it can be said that in most cases the menstrual blood-flow is lessened in the course of the disease even to the degree of complete amenorrhœa. Oligomenorrhœa and amenorrhœa, however, are secondary. They arise in consequence of the leukæmic blood-dyscrasia, just as they occur in chloro-anæmia, in the anæmia of obesity, in pulmonary tuberculosis and after severe hæmorrhages. With reference to sudden suppression of the menses, whose causal importance is insisted upon by Mosler, it is more probable that the same pernicious influence that effected the suppression at the same time produced the leukæmia.

It is alleged that among women the climacteric period has the greatest number of cases, and Mosler goes so far as to attach causal significance to the senile retrograde changes in the genitalia. But it is irrational to suppose, as he does, in a single case that the numerous severe labors and abortions with considerable loss of blood should first avenge themselves at the menopause instead of immediately upon the reception of the injury. And, in general, it may be remarked that the recorded cases furnish no evidence that can incriminate the change of life.

No evidence whatever has been presented to prove a connection between primary affections of the ovaries and secondary leukæmia. It has been shown, however, that in the course of leukæmia these organs, or their analogues, are sometimes involved. Hérard demonstrated the formation of lymphomata in the ovaries in one case; Robin, in the testicles; Gillot, in the mammary glands.

The coincidence of pregnancy and leukæmia is rare. Still, in the cases of Cameron, Greene and Sänger conception occurred. Accordingly, the conclusion is justified that leukæmia, as such, does not inhibit capability to conceive, but, at the most, limits the function, though even limitation is not probable, since repeated conceptions have been observed in leukæmia.

From these considerations the opinion seems justified that disturbances of menstruation, of ovula

tion and of conception in leukæmia have either a secondary significance or are entirely independent of the disease.

Turning now to the connection between pregnancy and leukæmia, it seems to me that the evidence in hand does not warrant Sänger's absolute denial of all causal relation.

The history of my case is briefly as follows:

Mrs. F. G., thirty-four years old; born in Boston of German parents; wife of a mechanic; VI.-para. When in health a large, fine-looking woman, five feet four inches in height, 150 pounds in weight. Menstruation, established in sixteenth year, was regular every four weeks, painless and of three days' duration.

No serious illness during girlhood with the exception of an attack of "inflammation of the bowels" that lasted six weeks during her fourteenth year. No history of syphilis, alcoholism, injury nor of rheumatism. Patient has lived in Boston, Mass.; Milwaukee and Menasha, Wis., and in Chicago, and never suffered from malarial infection.

Married Jan. 12, 1875, while in her twentieth year.

First child, male, born February 1, 1876, died of cholera infantum when eight months old (Dr. Root's certificate).

Second child, male, born September 7, 1877, nursed sixteen months; living and in health.

Third child, female, born November 12, 1879, nursed sixteen months; living and in health.

Fourth child, male, born May 4, 1882, nursed eighteen months; living and in health.

Fifth child, female, born December 12, 1886, nursed during her sixth pregnancy up to and on the morning of her confinement, July 8, 1888; child is now living and in health.

Sixth child, female, born July 8, 1888, small (premature). This child she was not able to suckle. At the end of the first week the child was artificially fed and died in convulsions at the end of the third week.

All her labors were easy and rapid. She was attended exclusively by a midwife. No miscarriages. With the exception of the sixth all the children large and vigorous. The four survivors, seen and examined June 1, 1890, present every appearance of health.

The course of the sixth pregnancy was normal. Three weeks before the sixth labor patient was a large and apparently healthy woman, with well-developed bust, and weighed 158 pounds. At this time she had a photograph taken, because, to use her own words, "she never looked so well."

Sixth puerperium, with the exception of the failure of lactation, was apparently normal. At the end of ten days she was up and at work as usual. At this time she first noticed stinging paroxysmal pains in the region of the left hypochondrium, although no tumor was perceptible. About six weeks after labor, August 22, 1888, menstruation was reëstablished, but was very scanty.

Menstruation for the second and last time, January 2, 1889: scanty.

Pains of a lancinating character in the region of the spleen became more severe, the loss of weight was progressive and weariness and general malaise became marked. About eight weeks after this labor she first noticed, and called to her husband's attention, a painful lump in the region of the left hypochondrium, which seemed to grow in size from week to week. Finally she consulted her physician, Dr. Glenn M. Hammon, of Chicago, who made an examination, January 21, 1889. He writes: "I found a large, densely hard nodular mass extending downward from the spleen and filling nearly the whole of the left half of the abdominal cavity. It was easily outlined because of the emaciation. There were no other glandular enlargements. There was considerable pain of a lancinating character." The case came under my observation January 31, 1889, and remained under my control for four weeks. Patient greatly emaciated, pulse 116, temperature 100.3° F. Heart, lungs, and liver negative. Urine free from sugar and albumin. Palpation of the abdominal tumor, rendered easy by the disappearance of the panniculus adiposus and by the marked diastasis of the recti, revealed an enormously enlarged spleen that filled out the left half of the abdominal cavity and below the navel extended obliquely to a point near the right iliac fossa. The hilum and the free notched anterior margin were easily outlined. The organ, symmetrically enlarged and immobile, was painful spontaneously and on pressure. There were some ascites and slight œdema of the legs and feet.

Pelvic genitalia absolutely normal.

Lymphatic glands and long bones negative.

A drop of blood, notably viscid, showed an enormous increase of the white corpuscles. The white corpuscles apparently equalled in number the red disks.

Diagnosis.—Leukæmia lienalis.

February 4, 1889, Dr. Frank Billings saw the case with me, and together we made a careful examination of the blood.

Blood-count (Hayem's hématimèter).—Red disks, per c.mm., 3,255,000; white corpuscles, per c.mm., 1,178.000; ratio of white to red as 1 : 2.7+.

On account of the viscidity of the fluid, due to the increase of white corpuscles, we encountered difficulty in the estimation of the hæmoglobin by Gowers's instrument. After many trials, however, we were successful, and fixed the quantity at 50 per centum. At this time we went over the history of the case and made a thorough physical examination, but discovered nothing new. We detected no enlargement of lymphatic glands, no change in the bones.

Retina not examined.

Family history good. Both parents aged, but in health. Blood of father and only sister (II.-para) upon examination, normal.

Prognosis.—Absolutely unfavorable.

Treatment.—Nutritious food, arsenic, iron, anodynes.

Subsequent course of disease. — February 11. Paroxysms of terrible pain; vomiting large quantities of blood. Diarrhœa; dejecta streaked with

blood. Rapid progressive emaciation. Pain always referred to the splenic tumor. Dr. J. M. Hutchinson, of Chicago, who saw the case later, kindly informs me that the paroxysms of terrible pain, always accompanied with violent vomiting, continued, the tumor increased in size, considerable ascites and œdema of the feet and legs developed; and that cachexia and emaciation progressed.

A few days before death patient weighed less than 100 pounds.

She remained conscious to within three hours of death, which occurred June 27, 1889. Autopsy could not be obtained.

This case presents several points of interest:

1. The certificate, returned to the city Board of Health, I am informed, assigns cancer of the spleen as the cause of the death of this woman. Now, as an ingenious figure of speech, it may be permissible to speak of leukæmia as carcinoma of the blood (Bard), or as sarcoma of the blood (Sänger), but it is a gross error to call a leukæmic spleen a cancer. Under adequate microscopical examination of the blood is it not possible that some of the examples of splenic cancer and of ague-cake reported here and elsewhere might be resolved into instances of leukæmia?

2. Exploratory laparotomy was actually proposed and very seriously considered in this case. But in view of the professional insanity that has attended the evolution of the "abdominal instinct," this proposal cannot be regarded as phenomenal. Splenotomy, according to Collier, has been performed in 29 cases. Out of these, 18 were in cases of leukæmia —all patients died immediately after the operation. Of the rest, 61 per cent., recovered. The operation of extirpation of the leukæmic spleen is justly looked upon as an art error.

3. The family history of the patient is good. As before remarked, the father and mother, though aged, are in excellent health. The only sister is the healthy mother of a robust child. The patient's four living children are sound and active.

4. The history of the case seems to point to some necessary relation between pregnancy or between prolonged lactation during pregnancy, or both these factors, and the leukæmia. The evidence, indeed, is only probable, but it is sufficient to create a presumption. As pertinent to the discussion, I beg to submit the following sentence, taken from the Introduction of Butler's *Analogy*:

"In questions of difficulty, or such as are thought so, where more satisfactory evidence cannot be had or is not seen, if the result of examination be that there appears upon the whole the lowest presumption on any one side and none on the other, or a greater presumption on one side, though in the lowest degree greater, this determines the question even in matters of speculation, and in matters of practice will lay us under an absolute and formal obligation, in point of prudence and of interest, to act upon that presumption or low probability, though it be so low as to leave the mind in very great doubt which is the truth."

This view of the nature of the case receives some support from its antecedent probability. During gestation the organs of the blood-glandular system, notably the spleen, the thyroid and lymphatic glands, increase in size and their functional activity is augmented. According to Birch-Hirschfeld,[1] the normal average weight of the spleen in the non-gravid woman is 140 grammes, while at term it is 180 grammes. Virchow says that the number of white corpuscles is normally increased during pregnancy. Sänger, indeed, questions the evidence upon which this assertion rests, but he does not prove that the physiological leucocytosis does not occur. Clinical experience teaches that physiological processes are liable to undergo pathological exaggeration during pregnancy. Restricting attention to the blood we have examples of the truth of this statement in the chlorosis, hydræmia, and pernicious anæmia of the gravid woman. It is conceivable that under certain conditions the physiological leucocytosis of pregnancy and the normal splenic hypertrophy may undergo pathological exaggeration and terminate in leukæmia. This notion is not forced nor strange, but is altogether in harmony with what we know of the constitution and the course of nature.

As to the exact effects of lactation during the usual period, upon the blood-glandular system but little is known, and our ignorance is still greater when we come to lactation during pregnancy. From carefully conducted examinations of the mammary glands of guinea-pigs, during and after pregnancy, Rauber concludes that:

"Milk owes its origin to the entrance of countless leucocytes into the lumen of the gland-vesicles. The emigrated lymphoid elements penetrate the alveolar walls, passing through the single layer of epithelial cells which lines them. Arrived in the interior of an ultimate acinus, the leucocytes undergo fatty metamorphosis and thus furnish the most essential and characteristic ingredient of milk, viz., the milk-globule."

Satterthwaite says:[2]

"Thus the primitive opinion advanced by Empedocles, describing milk as white pus, is in a measure revived, and milk is held to be directly derived from the white corpuscles of the blood."

But, as at present informed, Rauber's ingenious hypothesis has never been definitely corroborated, and it is not positively asserted that in this case the excessive demand by the lacteal secretion upon the white corpuscles was the cause of the splenic tumor.

The probable time of the commencement of the leukæmia in this case coincides with the latter days of the sixth pregnancy. This is the period

[1] Berliner klin. Wochenschrift, 1878, p. 324.

[2] Manual of Histology, 1881.

when the blood-glandular organs are most severely taxed by pregnancy itself. Add to this the additional strain of suckling a vigorous babe, and it seems that there is presented a cause adequate to the phenomenon.

This proposition rests chiefly upon the history of the case, obviously a precarious basis. Still, three weeks before labor the woman was the picture of health, as shown by her photograph, and by her weight, 158 pounds. Soon after labor and after the failure of the milk the pains were felt in the side, and the splenic tumor, small then, appeared. All these facts fix with tolerable accuracy this time as the date of the commencement of the disease. This impression is confirmed by the duration and by the character of the course of the disease. The patient died eleven months and nineteen days after her sixth confinement, and the course of the disease was steadily progressive.

Out of the 63 cases tabulated by Gowers, the duration of the disease was under a year in the 13 examples whose symptoms more or less closely resemble the clinical picture of this case, and in general the average duration of the malady may be reckoned as between one and two years (Eichhorst).

The history of the case offers no other explanation of the leukæmia. Trauma, syphilis, alcoholism, can be absolutely excluded. The patient never resided in a malarial region, and to the best of her knowledge never suffered from malarial infection.

A few cases have been published that seem to point to a causal relation between some phase of the puerperal state and leukæmia. Sänger, indeed, insists that this connection has never been established. On the one hand, he thinks that pregnancy does not affect the origin or course of leukæmia; on the other hand, he seeks to prove that leukæmia affects pregnancy in the determination of premature labor only indirectly by the greatly increased intra-abdominal tension, on account of the presence of the splenic tumor, ascites, meteorism of the intestines and the like. "The leukæmic quality of the blood, as such," he writes, "does not need to be invoked in explanation." But, as before remarked, the weight of evidence, as it seems to me, is in favor of the older view, of some necessary reciprocal relation between pregnancy and leukæmia. For my purpose, it is sufficient to mention merely one old and three new cases.

Leube[1] and Fleischer describe a case of a myelogenic leukæmia. A woman, strong and healthy up to the time of examination, developed four months after a normal labor, signs of a somewhat rapidly increasing leukæmia, without demonstrable cause. There were impairment of nutrition and strength, syncope, headache, anorexia, and also painfulness and swelling, which finally in part disappeared, of the left lower extremity. Five weeks later, there were signs of a high degree of anæmia, blowing murmur over the heart and a small compressible pulse. No enlargement of spleen, liver, or lymphatics. The number of red corpuscles was significantly decreased and there were both relative and absolute increase of the white corpuscles. The left tibia and left tarsus were painful on pressure. On account of rapidly increasing gangrene of the skin, amputation of the left foot was performed and was followed by death, six days later. Section revealed extreme anæmia of all internal organs, advanced degeneration of the cardiac muscle and chronic ulcer of the stomach, but no change in the liver, spleen or lymphatics. The bone-marrow was red and hyperplastic, with numerous nucleated red blood-corpuscles (transition forms, and numerous marrow cells).

According to Osler's[1] interpretation:

"This was no doubt a case of post-partum anæmia aggravated by the presence of ulcer of the stomach, and the great interest of the case lies in the transition of the anæmia into leukæmia."

In Cameron's[2] case, there were presented among others, the following points of interest:

"1. Splenic tumor was first noticed by her at the beginning of her sixth pregnancy."

"2. Spleen and liver always enlarge during pregnancy and become tender."

"3. The progressively enormous increase of white cells and decrease of red cells, as pregnancy advances.

"4. The rapid subsidence of œdema and dyspnœa after the termination of labor, together with the rapid increase of red and decrease of white cells."

Of the later course of this case, Dr. Cameron, under date of June 3, 1890, writes me:

"My patient is still living and has been confined twice since the Washington meeting. The first time she made an excellent recovery and regained her health so much that she was able to do all her own housework. The child was premature and died very shortly after birth, but was quite free from all trace of leukæmia. During her last pregnancy her health was poor. She became very anæmic and suffered so much from dyspnœa, palpitation, and threatenings of heart-failure that I was obliged to induce labor about the seventh month. The fœtus had perished some days previously. She barely escaped with her life, and is slowly going down-hill. The splenic tumor and her blood-count remain about the same."

James L. Greene's[3] report of two cases, of leukæmia, so sharply criticised by Sänger, while defective, is still of a certain value. His first case, during a first pregnancy, was an example of acute lienal leukæmia that was fatal within six months of the apparent outset. Although malarial infection cannot be

[1] Ein Beitrag zur Lehre von der Leukæmie, Virchow's Archiv, lxxxiii. p. 1124.

[1] Pepper's System of Medicine, vol. iii. p. 920.

[2] Transactions of the International Medical Congress, Ninth Session, Washington, 1887. Vol. ii. p. 330.

[3] New York Medical Journal, February 11, 1888. p. 144.

absolutely excluded in this case, the course of the disease creates the presumption that malaria, if present, must have played a minor *rôle*. It is to be hoped that the history of Greene's second case will be filled out in the near future, since, as at present described, the diagnosis of leukæmia, to say nothing of the variety, is not established. The case is that of a young primipara, the sister of the patient of the first example, who suffered from symptoms pointing to leukæmia. Upon the artificial induction of abortion, the patient promptly recovered. Of this case, Dr. Greene, under the date of May 30, 1890, writes me:

"The second case mentioned by me, Mrs. C., has conceived since the report was published, and with this condition returned all of the symptoms of leukæmia. An abortion was produced and she regained her health as before."

On account of the antecedent probability of the view, on account of the coincidence of the apparent onset of the disease with the later days of pregnancy, on account of the absence of any other demonstrable adequate cause, and finally, on account of the evidence accumulated from the cases cited, it seems to me to be highly probable, that in this case, the leukæmia sustained some necessary relation to pregnancy, or to prolonged lactation during pregnancy, or to both these factors.

2330 INDIANA AVENUE.

RECENT OBSERVATIONS IN THE ETIOLOGY AND TREATMENT OF MIGRAINE.[1]

BY WHARTON SINKLER, M.D.,

PHYSICIAN TO THE PHILADELPHIA HOSPITAL AND TO THE INFIRMARY FOR NERVOUS DISEASES, ETC.

IT has seemed to me well to gather together some of the experience of the past few years in the treatment of migraine, and to cull from the journals and elsewhere what is of value in regard to conditions which may cause it.

This form of headache is of unending interest to the medical profession, for its cure or the alleviation of the paroxysms is a constant problem. Moreover, as Gowers remarks, "The disease is often associated with high intellectual ability and many distinguished men have suffered from it and have supplied more careful observations of the subjective symptoms than we possess of any other malady." We may almost say of it, as Sydenham said of gout, that "More rich men than poor men and more wise men than fools, are victims of the affection." Among the prominent men who have had migraine are DuBois-Reymond, Dr. Fothergill, Dr. Lauder Brunton, Dr. Anstie, Sir John Herschell, Sir George Airy and his son, Dr. Hubert Airy, and we all have among our own medical friends many who suffer from attacks. It is by no means, however, confined to the more prosperous classes, for we meet with it in all conditions of men and at all ages.

The attacks of migraine from uterine disorders have been known to the profession for years, and there is a large amount of literature on the subject. Recently much has been written on headaches from eye-strain and many of these are of the hemicranic type. Numerous cases have been reported which have been relieved by correcting refraction errors of the eye. The connection between migraine and disorders of vision has been pointed out by several authorities, amongst others, Mr. John Tweedy, Dr. Savage,[1] Mr. Carter, Dr. William Thomson, Dr. S. Weir Mitchell,[2] and quite lately, by Dr. George F. Stevens,[3] whose writings on the relief of various disorders of the nervous system by tenotomy of the ocular muscles have attracted much attention. This author thinks that ocular defects play a conspicuous *rôle* as causative conditions in migraine. He refers to a few cases of "blind headache" in which the fundus of the eye was examined during the period of visual disturbance preceding an attack. The retina has been found pale and brilliant, the optic nerve unusually white, and the main arteries somewhat irregularly contracted in their course. In these cases the field of vision was found to be contracted in a striking manner, in some cases, one-half of the field being lost, and in others the central field was gone and imperfect sight remaining in the periphery. He finds that, unlike ordinary forms of headache, hemicrania does not easily yield to the simple measure of adapting glasses to correct refraction errors. It is often caused by a complication of refraction trouble and muscular insufficiency. This requires tenotomy and suitable glasses. Mr. Bendelack Hewetson[4] has removed migraine by paralyzing the power of accommodation by atropine. Henry S. Oppenheimer[5] considers eye-strain to be a frequent cause of headache and believes that it is often overlooked. He relates a case of headache and severe tinnitus aurium cured by the proper application of prisms combined with convex cylinders.

He recommends in the treatment of headaches from eye-strain, first, that all hygienic and medical indications be carefully carried out; secondly, a most careful correction of the refraction and accom-

modation; thirdly, correction of muscular insufficiencies by prisms, beginning with a low degree and, when necessary, increasing in power; and should this prove insufficient, tenotomy.

T. Lauder Brunton[1] speaks of migraine from caries of the teeth. He says:

"The most common causes of headache, indeed, are decayed teeth and irregularities of vision. When the teeth are decayed rinsing out the mouth with a lotion of bicarbonate of sodium, or applying a little cocaine to the exposed pulp will relieve the headache."

He refers to his own case in which, during the attack, the pain was limited to a spot in the left temple. On one occasion he accidentally discovered, under the angle of the jaw, a small gland, which was hard and painful to the touch. This led him to examine his teeth, and these he tested by percussing with a steel instrument until he discovered a tender spot on the last lower molar on the left side. He went to a dentist who found that caries had begun at that spot but had, as yet, caused no cavity.

He also describes the case of a clergyman who began to suffer from headaches so intense as completely to incapacitate him. He took various medicines in vain and went for a continental tour, but came back little benefited. Dr. Brunton saw him shortly after his return and examined his teeth, all of which looked healthy. He then took a steel bodkin and probed and percussed each tooth in succession until he came to one which was tender. The dentist found that this tooth was carious. It was properly filled, and the headaches disappeared.

He further says:

"In cases of headache depending upon a decayed tooth when no toothache is felt, it is not improbable that the irritation in the tooth does not give rise directly to the sensation of pain in the head, but does so by acting through the sympathetic system on the vessels, so as to cause the spasm which leads to the sensation of pain."

J. S. Dixon[2] reports several cases in which the removal of carious teeth stopped attacks of hemicrania.

Dr. Louis Starr[3] speaks of headaches being frequent in children during the period of second dentition. He says:

"Headache is common. The pain is usually temporal or unilateral. It may be seated, however, in the occipital region or in different parts of the face, and sometimes shifts suddenly from the occiput to the temporal region. One or more painful points can often be detected and generally there is a hard, tender, markedly enlarged lymphatic gland in the sub-maxillary or cervical region."

He suggests that the method of production of the headache is one of direct nervous connection, the sub-maxillary ganglion acting, in the case of the lower teeth and the spheno-palatine in the case of the upper, as mediums of transfer of irritation to the vaso-motor nerves.

The nose and ear are now recognized as means by which external irritation may operate in producing headaches. Dr. Brunton[1] finds that in his experience headache depending on disease of the nose is at the top of the head just behind the commencement of the scalp, and headache here should always lead to an examination of the nose.

Dr. Hack, of Freiburg, (quoted by Brunton), has observed several cases, both of migraine and of frontal headache, depending upon congestion of the mucous membrane covering the anterior turbinated bones, and has been able to effect a radical cure in several cases by the application of the galvano-cautery to the inflamed and swollen mucous membrane.

Thomas E. McBride[2] relates four cases of migraine which were cured by relieving the post-nasal catarrh which had existed in each case.

Harrison Allen, in a paper read before the Philadelphia Neurological Society.[3] refers to a patient in whom merely touching the right middle turbinated bone with a probe instantly caused intense vertex pain. He reports a second case in which there were attacks of general headache and clavus over the right parietal eminence. In this patient he found disease confined to the middle turbinated bone on the right side. He also mentions the case of a lady in whom there were frequent attacks of "sick headache" which were dependent upon deep-seated infiltration of the pharynx. The headaches were removed by curing the pharyngeal disease.

John O. Roe[4] has contributed a paper on "The Frequent Dependence of Persistent and So-called Congestive Headaches upon Abnormal Conditions of the Nasal Passages."

Most of his cases had constant, dull, general headache, but in two or three the attacks were migraine, and were accompanied with nausea and vomiting. In all some obstructive disease was found in the nose and removal of the obstruction was followed by relief from the headaches.

Migraine has been known as a disorder of childhood for many years and I have elsewhere pointed out its frequency in very young children.[5] I have seen at least one case in which a child of two years had periodical attacks, with every characteristic of mi-

graine. A medical friend has described to me the case of one of his own children whom he believes to have had attacks of hemicrania from the age of two years. Gowers[1] says one-third of the cases begin between five and ten years of age.

Russell Sturgis[2] has described a form of recurrent headache in children, which he considers to be similar to the migraine of adults, with the difference that the pain is more likely to be across the forehead, and is less often confined to either side of the head than that of migraine. He describes these attacks as occurring in children of a nervous temperament, who sleep poorly, with bad dreams and night terrors, and who are fretful and often chilly and have a heavy expression about the eyes. There were in many of his cases optical illusions of sparks or spots, and bands of color. The treatment which he has used successfully in some twenty cases, consists in the administration of ten minim doses of the fluid extract of ergot, more being added if there is coëxisting anæmia. The ergot should be continued for several weeks after the cessation of the headaches.

Migraine sometimes begins late in life. A patient, whose case I shall report later, never had an attack until his thirty-eighth year, and Gowers speaks of a man in whom the attacks began at sixty years.

The visual phenomena of an attack of migraine have been discussed for many years. Lately some interesting cases of transient hemianopsia and unusual forms of scotomata have been reported. Dr. de Schweinitz has kindly given me an account of two cases in which the form of scotoma was unusual. In one it was described as being like the wavy appearance of heat rising from a chimney. The cases are as follows:

"A man, aged thirty-two, whose family physician reports general health good, and who, as far as my own examination is concerned, has no organic disease. For a number of years this patient has had attacks of typical migraine; the invariable prodrome is an appearance as if heat were rising in the air, which is followed by numbness of one hand, or else numbness of the tongue and, although of this I am not absolutely sure, aphasia. This condition lasts from fifteen to twenty minutes, sometimes as long as an hour, and is succeeded by a terrific explosion of hemicrania. His attacks average one a month, but they have occasionally come as often as once in two weeks. He has a moderately high degree of compound hypermetropic astigmatism, together with insufficiency of the internal recti of eight degrees in accommodation. There are no other muscular anomalies. He is at present under treatment for the eyes.

"The other case is one of a man aged forty-seven, typically neurasthenic, and of bilious temperament, who, for many years, has had severe migraine, the attacks averaging one every two weeks. He has no definite or always present prodrome, but in a certain number of instances this has consisted of a large, dark, circular object, composed from within outward of a dense black rim, a broader grayish-black circle, a central nucleus of yellow color, and a nucleolus of dense black. It is needless to remark that I, not he, have used these technical terms to describe it, but you observe that this curious appearance which he drew for me, contains the components of a compound cell, the dark outer rim corresponding to the capsule, the gray portion to the cell contents, the yellow spot to the nucleus, and the dark spot to the nucleolus. This patient has a high mixed astigmatism, with insufficiency of the external recti of four degrees."

Dr. Charles A. Oliver kindly referred to me a case of migraine in whom there existed that rather unusual condition of contraction and dilatation of the pupil known as hippus, in connection with the attacks of migraine, and in whom there were other interesting visual phenomena accompanying the attack. The following notes were made by Dr. Oliver:

"*January 8, 1886.* L. L., aged twenty-five years, unmarried.

"For two weeks past she has had a spasmodic action of the right iris, causing the pupil to dilate and contract irregularly; this spasmodic action being felt by the patient as a twitching or a series of movements. During the past eleven months she has had a number of severe attacks of migraine, blindness appearing simultaneously before the right side of each field of vision and quickly moving across to the left side, lasting for fifteen minutes and followed by clearing up of the visual fields in the same sequence; that is, commencing at the right periphery of each field and ending on the extreme left side. The attacks terminate with the usual signs of headache, nausea, etc. She has had the headaches, which have been worse at the time of menstruation, for several years. She complains of asthenopic symptoms and she has never worn glasses. She had four brothers and one sister, she being the third child. A younger brother had a 'cast' in his eye and the mother has worn glasses for years. The patient was overworked, neurasthenic, and her menses were scanty and irregular. Ocular symptoms show:

$$\infty \text{ O. D. V.} = \frac{5}{7}, \frac{1}{2}? \quad \text{Sn. } 1\tfrac{1}{2}\ 6''\text{–}26''.$$

$$\infty \text{ O. S. V.} = \frac{5}{7}, \frac{1}{2}. \quad \text{Sn. } 1\tfrac{1}{2}\ 6''\text{–}26''.$$

"Eyes are slightly *in* under hand-cover.

"The ophthalmoscope showed gray disks with a tortuous condition of somewhat undersized retinal veins, with the characteristic changes of disturbed ametropia. Patient was advised an estimation and correction of refraction error, but she refused to have glasses, thinking that rest from work would relieve the necessity for wearing them.

[1] Diseases of the Nervous System, 1888, p. 1172.

[2] Archives of Pediatrics, 1889, vol. vi. p. 293.

"*November 5, 1886.* The last attack began as a large, central scotoma, which she says was about the size of a silver half-dollar, associated with fronto-temporal pain on both sides and lasting about twenty minutes, followed by numbness of the left upper extremity, commencing in the ring and little finger.

"Patient failed to report for over two years, when she stated that she had been free from attacks until the day when she was seen. This attack appeared as a central, blind area which was not surrounded by any brilliant lines or zigzags. This lasted for about fifteen minutes, and was followed by giddiness but no numbness. The right-sided hippus was again complained of, and upon careful study was found just as pronounced as at the previous examination. The iris excursions which were quite extensive were found to be fifteen times in each half minute upon monocular exposure, and but six times in the same length of time upon binocular exposure.

"The patient was next seen April 29, 1890. No attack until three weeks before, when one unexpectedly appeared four days before menstruation. Patient was then highly neurasthenic and nervous."

In June, 1887, Dr. S. Weir Mitchell read at the College of Physicians[1] a paper on some remarkable visual hallucinations, which took the place of the ordinary balls of light and zigzag lines which are so commonly met with as a precursor of an attack of headache. He relates four cases, the first of which is of so much interest that I will repeat it in full:

"Miss W., aged thirty, was in good general health, and able to bear great fatigue, and to use her mind and body incessantly as a teacher. About once a week for many years she had attacks of migraine of great severity. When nineteen years old she began, just before the headaches, to see a bright, gold-tinted cloud, and with it an appearance of parti-colored rain. There was most clouding of vision when the sequent pain was over the right eye, and these visual phenomena were not constant. When twenty-eight years old, and still subject to prolonged headaches, the attacks changed their type. After a few weeks of freedom, one day when going up-stairs she was abruptly aware of being accompanied on her left by a large, black, and very hairy dog. In some alarm she ran into a room and sat down, but still found the dog beside her. Being a woman of courage, she put out her hand to touch it, but could feel nothing, although her ghostly companion was still visible. At this moment severe pain began over the left eye, and the dog was gone. The attacks recurred at intervals, as well as the now ordinary brow-pain, without the dog vision, but the 'dog-headaches,' as she called them, were always the most severe. The visual phenomena left her after some years, but as she went to live abroad I lost sight of her. I should add as a curious detail that nearly always, but not invariably, the dog appeared as she was going up-stairs.

"In the second case the apparition consisted in the appearance of a sister who had long been dead.

"The first time it appeared the patient, who was in the fourth month of lactation, was dressing in front of a mirror when she was suddenly aware of the dead sister standing beside her. The vision was followed by a severe pain in the left eye, lasting for many hours, which ended with an attack of nausea and a great flow of pale urine.

"In the third case, the form of a near relative appeared just before the attack of headache, and faded as the pain increased, but she was left for some days with a strong desire to kill the person whose image she had seen. The patient came of a highly neurotic family. Two brothers died of epilepsy, and two sisters had been insane. The patient afterward had attacks of melancholia, but ultimately made a complete recovery after removal of both ovaries.

"In the fourth case a man of thirty saw a variety of visions, complex figures of brilliant pink or red, multiple red circles in rapid rotation, which apparently came from the distance. Once there appeared a crescent of silver on the wall, suspended from which were numerous heads in profile. Some were strange to him, and some the revival of faces which had long been forgotten. In one attack a red spider appeared which merged into a series of rectangles, revolving in swift motion."

De Schweinitz[1] reports six additional cases of migraine hallucinations of vision which preceded or accompanied the attacks. In one of these patients a large green snake was seen just before the attack. In another, marked visions of animals, always either mice or dogs, were associated with headache. Once in the morning the vision took the form of the water-pitcher in the room, through the handle of which a constant stream of running mice playfully chased each other. Once in church the vision was that of a small black dog, that curled himself at her feet.

The hallucinations of vision in connection with epileptic attacks have been observed by many authors to resemble markedly those described by Mitchell and de Schweinitz. I have recently seen a patient who had some interesting visual phenomena connected with epilepsy:

Mrs. A., aged forty, has three children, and has had three miscarriages. There is no neurotic family history, and she has never been subject to headaches. From the age of nine or ten years she has had attacks in which everything seems far off, or, as she expresses it, "like looking through the large end of an opera-glass." There always appeared in these attacks a face with unpleasant expression, which was very distinct for a time, but gradually faded away. She was not unconscious during the attack, but felt powerless to move or exert herself, and would call to any one in the room to shake her so that she might regain self-control. The attacks continued with greater or less frequency until November, 1889, when she

[1] Neuralgic Headache with Apparitions of Unusual Character. Transactions of the College of Physicians of Philadelphia, vol. ix. p. 175.

[1] University Medical Magazine, May, 1889, p. 450.

had an attack of epilepsy (*grand mal*) in her sleep. Again, in April, she had another attack while driving in her carriage. These are the only attacks of *grand mal* which she knows of having had, and both were preceded by the vision of the unpleasant face.

P. Blocq thinks that ophthalmic migraine should be separated from the other migraines. This variety has pain in the head and visual troubles in the simple form, to which are added at times aphasia and sensory or motor troubles. He reminds us that Charcot has already called attention to the fact that ophthalmic migraine may be prodromic to general paralysis. Therefore, its liability to this serious ending must be borne in mind. Blocq relates three cases of migraine associated with general paralysis, the first of which is a typical one of ophthalmic migraine, reported by Charcot, the second reported by Parinaud, and the third case by himself. In all the cases heretofore described the attacks of migraine had preceded the general paralysis, but in the case reported by Blocq the attacks of migraine accompanied the paresis.

Suckling[1] has reported a case of migraine in a youth of eighteen years, in which the attacks were followed by paralysis of the upper eyelid on the left side, which lasted forty-eight hours. The patient had been subject to attacks of sick-headaches since infancy, and the temporary paralysis of the third nerve had occurred since that time. The paroxysms lasted two days, during which time the patient was confined to bed, and was unable to eat. There was a nasty taste in the mouth, and a copious flow of saliva.

The periodicity of the attacks of migraine has been known for many years. It is spoken of by Liveing,[2] but I can find only one writer besides myself[3] who has observed that the attacks may recur on a certain day of the week. Tissot[4] says that Salius relates the case of an Italian monk who, for three years and seven months, had an attack of violent hemicrania every Monday, the attacks lasting from twenty-eight to thirty hours.

Liveing, who refers to Tissot's case, thinks that an exact periodicity like this is probably due to the diet or engagements of the day preceding the attack. This is undoubtedly the case in many instances, but in some of the cases which I have seen there was nothing done on the day previous to the attack different from that done on any other day of the week. I will relate some examples of cases of this kind which I have seen.

[1] Brain, vol. x. p. 241.

[2] On Megrim or Sick Headache, p. 36. London, 1873.

[3] Pepper's System of Medicine, vol. v. p. 407. Philadelphia, 1886.

[4] Traité des Nerfs, vol. viii. p. 102. Lausanne, 1788.

CASE I.—Miss C. J. H., aged thirty years, teacher. Menstruation regular, painless. From twelve until twenty-two years of age she had attacks of "regular sick-headache." For the past eight years the attacks have been confined to the left side of the head, chiefly in the left brow. The attacks recurred with great regularity and came always either on Monday or Tuesday. The attacks were often brought on by fatigue or by a draught of cold air.

Cannabis indica was given in increasing doses and the patient was greatly relieved. The periodicity of the attacks was broken up and the intervals became from eight to ten weeks.

CASE II.—Mr. A. H. W., aged thirty years, temperate, uses tobacco in moderation. He has a sister who frequently suffers from attacks of headache which come almost always on Sunday.

Mr. W. had sick-headaches in childhood, and when about sixteen years of age began to have attacks in which the pain was confined to one side of the head. They occurred almost every Sunday morning for several years. He usually got up with a dull headache and soon after breakfast had scotomata (red and yellow spots), floating at the upper and external angle of the eye. This was followed by violent pain in one brow or in the occiput. The attack would last eight or ten hours, terminating in vomiting or in a sharp attack of diarrhœa, after which he felt entirely relieved. Occasionally the crisis was accompanied by an exceedingly copious flow of urine. The patient usually rose at about 6.30 A. M., but on Sunday lay in bed until 9. This, and the culmination of a hard week's work, probably induced the headache. For the past two or three years his work has not been so hard and his life has been more regular: he now but seldom has a severe headache (not more than three or four in the course of the year), and his general health has become excellent.

CASE III.—Mr. J. D. F., aged forty-one. Married. A grain merchant.

He has had headaches since he was eight or nine years of age. The attacks were not periodical until five or six years ago when he became actively engaged in business. He then began to have attacks with regularity every Sunday. They usually came on about midday without ocular or other prodromes. The pain was always located in the occipital region and lasted with great severity for five or six hours when vomiting occurred, after which he was relieved of pain.

I gave him cannabis indica and regulated his diet and the attacks were very much relieved in frequency and severity. The Sunday attacks recurred for about nine months. He ascribed the attacks to the result of a week's hard work. As he expressed it himself, on Saturday night he would "unbuckle," feeling that his work was done until Monday. Instead of rising at six, as was his habit, he did not get up until nine on Sunday morning. He now very rarely has attacks and they are not so severe as formerly.

CASE IV.—Mr. J. M. H., aged fifty. Bookkeeper and has close desk-work. Of a nervous tem-

perament. His habits have always been good as to stimulants and he never uses tobacco. He had no headaches in childhood. Twelve years ago, at the age of thirty-eight, after a plain, wholesome dinner, he noticed waves and floating spots before his eyes. These were followed by a severe pain in the head. Since that time he has averaged five attacks in a year. The attacks are very much alike. They are always preceded by scotomata and occasionally there is partial hemianopsia. This is followed by pain over the entire head, which lasts for from twelve to fifteen hours. There is nausea, but no vomiting or crisis of any kind. The attacks almost always occur on Sunday. He rises later on Sunday than on other days, takes a bath about midday, and it is after his bath that he usually has the attack of headache. For some years he has had a permanent scotoma before the eyes. He does not notice it when he is at work, but when he is in a bright light or out of doors the spots are very bright, sometimes irregular in shape with a double outline and always seem to be falling.

Case V.—A. W., aged thirty-three years. Single. Seamstress. She has suffered from headaches since she was seventeen years of age. For some years her attacks have occurred about once a week and almost always on Sunday.

The attack is usually hemicrania, but the pain is occasionally over both eyes. Sometimes there are intervals of three weeks between the attacks, but on each of the last three Sundays she has had her usual form of headache. When at the seashore or in more robust health she has had less frequent attacks of headache.

Case VI.—M. C., aged thirty-five. Lady's maid. Both parents are dead. Father died of pneumonia, the mother in confinement. She has one brother and one sister. The brother is healthy. The sister is thirty-eight years of age and has always had violent headaches. For many years the sister had the attack on Sunday. Her occupation and mode of life on that day or the day preceding seemed to have nothing to do with the attacks.

The patient's headaches began with the catamenial period, and have always preceded the menses. About nine years ago she began to have headaches on almost every Sunday. There was no change in her manner of life at this time and for three or four years the attacks came with regularity on this day. Then she began to have them on Saturdays, sometimes for two or three months at a time. At present she does not have the attacks so often. She has been free from headache for as long a time as two or three weeks, but she always has an attack before the menstrual period, and does not remember to have ever gone longer than two months without an attack. She has been abroad two or three times, and then she escaped the attacks of migraine for a long period. Sometimes she wakes with pain in the head. At other times the attack begins later in the day. The pain is always confined to one side of the head, and generally the left side. She has no ocular symptoms except wavy spots like smoke. Occasionally there is vomiting, but not generally. The face and lips are pale during the attack. Her general health is good. Her catamenia are regular and she has no amenorrhœa. Her sleep is excellent and she is not overworked.

Treatment.—The drugs which have attracted the most attention of late are, undoubtedly, antipyrine, phenacetin, and the host of antipyretic and analgesic coal-tar derivatives, which have been introduced in the past few years. White[1] claims to have first used antipyrine in headache. At all events, it has been very universally employed in every variety of head-pain since its analgesic properties became known. T. S. Robertson[2] has used it in 88 cases of migraine; in 54 the action was satifactory in the course of from thirty minutes to two hours, and in 15 cases the administration of other drugs was rendered more effective by the use of the antipyrine. A negative result was obained in the remaining 8 cases. He recommends that 22 grains be taken at the onset, and in case the headache continues an additional dose of the same size. Bokenham[3] has used the remedy in 26 cases with entire success, but instead of using the large doses usually recommended, he gives only 3 or 4 grains, repeating the dose in an hour, if necessary.

Müller[4] has given phenacetin in migraine and various other forms of headache, but has found that large doses, as much as from 2 to 3 drachms, have been needed to produce good results.

Pesce has used[5] antifebrin with advantage in migraine. P. Guttman[6] uses phenacetin in small doses and gets as good results as from the use of antipyrine. The great advantage that phenacetin has over antipyrine is that it is much safer, as it does not depress the heart. During the recent epidemic of "grip" phenacetin proved efficacious in relieving the violent headache associated with that disease.

Rabuske[7] after trying quinine, arsenic, caffeine, antipyrine, electricity, change of climate, etc., was successful in the treatment of a very bad case of long-standing hemicrania by the administration of 8 grains of phenacetin night and morning. The cure was effected after the sixth dose.

Antifebrin has been used quite largely of late. Faust[8] has found this remedy, in doses of ½ to 1 drachm, of great use, the headache being relieved.

A. L. Clark[9] has found that 8 to 10 grains of antifebrin will relieve pain in the head in twenty to thirty minutes. S. Merkel,[10] from an experience of

[10] Munchener med. Wochenschrift, June 12, 1888.

49 cases of migraine and headaches of like nature, considers this a valuable drug. James Little[1] recommends, in the treatment of migraine, that during the intervals between the attacks the following pill be given twice a day:

℞.—Arseniate of sodium . . $\frac{1}{12}$ grain.
Extract of cannabis indica . $\frac{1}{6}$ "
Extract of belladonna . . $\frac{1}{3}$ " —M.

He gives in addition to this 2 grains of valerianate of zinc twice daily. To cut short a paroxysm he gives 20 grains of the salicylate of sodium in a wineglassful of water made effervescent by the addition of a dessertspoonful of the granular citrate of caffeine, a second or third dose to be taken after an interval of two hours.

Nitrate of cytisine (a poisonous alkaloid extracted from the seeds of the cytisus laburnum) has been given by Kräpelin in the angio-paretic form with excellent results in two cases.[2] He gives it hypodermically and was led to use it on account of its power of causing contraction of the bloodvessels. In two cases of the spastic form of migraine in which he used it the symptoms were aggravated.

De Schweinitz and Lewis[3] had a certain amount of success in the treatment of hemicrania with the oil of eucalyptus, and I myself had two or three patients in whom this drug was of marked utility. These authors have lately told me that further investigation has proved that its value is by no means general, although certain cases are relieved by its use. In cases where migraine is associated with the gouty diathesis, treatment of the latter is attended with success as far as relief of the headache is concerned. Haig[4] states that he has relieved many attacks in this form of the disease by giving 20 to 30 drops of dilute nitro-muriatic acid in water, repeated once or twice at intervals of a half hour.

Cannabis indica, which has been given in migraine for many years, still holds a prominent place among the medicinal agents used in its treatment. For myself, I may say that I consider it of more value in the majority of cases of migrainous headache than in any other headache. It must be given for some length of time and the dose should be increased until slight toxic symptoms are felt. We must remember the great variability in the strength of the drug, and be careful to begin with a minimum dose. I have but recently seen a patient who had marked toxic effects from $\frac{1}{8}$ of a grain of the extract. Segnin[5] several years ago pointed out the benefit of cannabis indica in this form of headache and insisted on its long-continued use.

Dr. Richard Green, who first recommended Indian hemp in migraine,[1] has continued to use it with success. He maintains that its effect is not simply palliative, but curative, and that in nearly all cases it gives permanent relief.[2] E. J. Overend[3] believes caffeine to be as complete a specific in migraine as quinine is in malarial fevers. He is himself a victim to the affection. He advises the administration of citrate of caffeine in doses of from 3 to 5 grains as soon as the first indication of an attack is felt, and its hourly repetition until relief is experienced. Electricity is of more or less value and many cases have been greatly helped by galvanism. I have found this means of marked benefit, but have not depended upon it alone in any case. Labbé[4] has cured a severe case of eight years' standing by thirty-four applications of static electricity. A number of other new remedies have been used to a limited extent in this affection. Among them is exalgine, which I found of use in shortening an attack. Ringer has successfully used tincture of nux vomica in drop doses repeated every half hour.

Amongst the latest remedial agents proposed for the cure of migrainous attacks is hypnotism. In a work on the subject by Albert Moll[5] he expresses his belief that either post-hypnotic or auto-hypnotic suggestion may be used to cure this disease.

Most authors now agree as to the prime importance of hygienic measures in connection with any remedy used for the relief of this disease. Removal from care and work, with fresh air, good food, and change of climate will do more to relieve the frequency of the attacks than any drug. In connection with this the rest-treatment of S. Weir Mitchell is of the greatest value, and I have seen many cases of chronic migraine relieved by this means.

STUDIES IN THE ETIOLOGY OF MALARIAL INFECTION AND OF THE HÆMATOZOA OF LAVERAN.[6]

BY GEORGE DOCK, M.D.,
OF GALVESTON, TEXAS.

The present condition of the search for the *contagium vivum* of malaria is such as to make expedient the collection and recording of even isolated experiences. Proof in regard to the causal relation

[6] Read before the Section of Practice of Medicine, Materia Medica and Physiology of the American Medical Association, May 20, 1890.

of the organisms first described by Laveran is so strong as to be all but convincing, yet there are still certain links to be added to the chain of evidence. In bringing forward some observations of my own I shall omit a detailed account of the investigations of others, presuming that from the works of Councilman, Osler, Sternberg, and James, they are already known to the reader.

The observations to which I wish particularly to call attention are those which deal with the flagellate organisms; but partly to preserve a better order, partly as an additional contribution to the subject, I will give my general experience with the malarial parasites.

The observations here reported were made in Galveston, Texas and after I had become practically familiar with the parasites while acting as Dr. Osler's laboratory assistant. Malaria is uncommon in Galveston. Only three cases which could have originated on the island have come under observation. The other cases, thirty in all, came from various points of the interior of Texas, whose river "bottoms" have a well-deserved reputation as malaria breeding-places. These cases, with few exceptions, were seen in the hospital. In all of them some of every form of the parasite heretofore described by authors have been found. Most of the cases were seen but once, so that detailed studies could not be made. In 12 cases, however, I was able to make more extensive observations, amounting in all to over 50, in which the blood was examined in one or several preparations for from one-half to four hours.

To supplement this I must add another series of more than thirty cases of fevers of various kinds, including enteric fever, pneumonia, phthisis, septic conditions, etc. Some were suspected cases of malaria, and in them quinine had been used. In none of these were organisms found, nor anything (with an exception to be noted later) resembling them. I have also examined the blood of a large number of persons from the interior, some of whom had had chills, but at the time of examination were well; others of whom, though exposed, had never had ague—and in none did I find organisms, nor did ague occur in them as long as they remained under observation.

It is almost needless to say that in many cases the blood-examination led to important changes in the therapeusis. One of the most striking examples is the following: On February 13, 1890, I examined the blood of a foreign sailor just arrived from a South American port, who had had no chills, and on account of muscular pains was thought to have "grippe." Finding a number of nearly "ripe" plasmodia I diagnosed malaria and predicted a chill, which followed in seven hours. Quinine was given and the patient rapidly recovered without another chill.

In all cases I examined the blood from the fingertip, at the ordinary temperature. In some cases in addition dried preparations were made and stained, but I had no opportunity of making extensive investigations of that kind. Necessary as such studies are in determining some facts regarding the organisms, fresh preparations are for many reasons more valuable. In all the observations I used a Zeiss one-twelfth homogeneous immersion, ocular iv.

This seems the proper place to explain the above statement regarding the bodies resembling the plasmodia, but found in non-malarial blood. The exception alluded to concerns the unpigmented hyaline forms, which are sometimes simulated by certain appearances in the red blood-corpuscles. Some of these appearances are the so-called vacuoles; others, and more deceptive, are reflections caused by bosses on the surfaces of the corpuscles; still others, often seen in patients with hyperpyrexia, are caused by an increase in the biconcavity of the disks. All of these can be distinguished, with care and experience, from the true plasmodium.

For purposes of description the various forms may be classified into endoglobular bodies,[1] including the rosettes; free bodies, including flagellates and crescents. I shall follow this order as well as circumstances allow me.

With the bodies in the first class my experience has been similar to that of others. That is, I have found them in all cases of acute intermittent fever (not cinchonized) and in many protracted cases, and therefore look on them, on the whole, as the most important from a clinical standpoint. I have made several attempts to follow up Golgi's theory of the cyclical development of the plasmodium, the general truth of which is accepted by many observers. My own studies seem to prove the truth of Golgi's law, the practical importance of which is seen in the case cited; but most of my cases have been of mixed type and could not be left to their natural course long enough to establish the relations. I have not yet seen a case of quartan fever, and as all the many rosettes I have observed correspond with those Golgi has described as peculiar to tertian fever, this may be looked on as additional confirmation of his views.

In addition to those forms which perform the cyclical development, terminating in the segmentation of the rosettes, there are other endoglobular bodies which have a different series of phases. Many of these forms have been seen and described by various authors. Celli and Guarnieri looked on them as irregularly segmenting forms, and possibly

[1] Plasmodium malaria of Marchiafava and Celli.

as degenerations. Golgi described a very common form as a modification of division, but was uncertain whether it really was so. I have had very favorable opportunities for studying these bodies, and can confirm the observations of the authors named, as well as carry them further in some respects.

For convenience I shall speak of them as atypical plasmodia. They differ so much in minute details, that it is difficult to classify them, and indeed it would probably not be profitable to do so, since the differences can hardly be important. I have studied these bodies carefully in six cases, and have seen them in several others. Four were cases of acute vernal intermittent. In the two other cases there had been no chills for one month, but the temperature rose from one to three degrees at irregular periods. ("Dumb-ague," "bone-fever," of common parlance.) In the former cases there were typical forms, in the latter none.

These atypical bodies develop from small hyaline forms which cannot be distinguished from the typical plasmodia. The process of development is rather rapid, and is apparently unconnected with the course of the fever. They seem to have a special tendency to escape from the blood-corpuscles at early periods (Fig. 1). A little later than the

FIG. 1.

Changes of form in a small, free, hyaline body. Observation lasting five minutes.

stage shown in the figure, but where the corpuscle is not entirely destroyed, they form, on escaping, small spherical bodies, single or in rows connected by fine filaments, which have a fibrinous appearance. When the bodies reach a size almost equal to that of the corpuscle, they begin to assume the characteristic forms which distinguish them from the developing rosettes. That is, the pigment remains scattered, or, more frequently, fills a narrow zone near the edge, or outlines one, two, or three clear spaces in which dark globules can be seen. (Fig. 2, *a*, *c*.)

FIG. 2.

Developing atypical plasmodia. Nuclear bodies not shown.

The later stages of this process are not often seen in blood from the finger, which fact makes me think that part of the development of these bodies is in internal organs. This opinion is supported by the analogous development of the rosettes in the brain-capillaries in pernicious malarial fever; and I have seen the stage often enough to know that the substance of the corpuscle is gradually destroyed, a shell-like, colorless rim being left for some time, but ultimately disappearing. (Fig. 2, *b*.) Even before the final disappearance of the corpuscle a filament may form on the plasmodium (Fig. 2, *c*.), as I have seen in one observation. We thus have the free pigmented bodies, which, though varying in details, correspond in general to the later forms of the atypical endoglobular forms.

As my observations show a relation between these and the flagellate organisms, I shall consider other of their characteristics in connection with the latter.

Regarding the nature and origin of the flagellate bodies there still exist the greatest differences of opinion among authors. Laveran, in his earliest as in his latest communication, described them as the most characteristic and most important forms of the parasite of malaria, but admitted that they are comparatively seldom seen (in 92 out of 432 cases), as they appear only in a certain stage of development. Councilman came to similar conclusions, and found the bodies in 15 out of 20 cases in which splenic blood was examined. On the whole, the mass of testimony is against these views. Space does not permit a review of all that has been written on the subject recently, and I shall submit my own observations with only occasional reference to the contradictory or confirmatory studies of others.

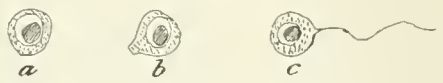
In regard to the occurrence of the flagellate bodies I can say from my own earlier experience that they were often overlooked because the bodies on which they form were mistaken for pigmented leucocytes. It is remarkable how cautious in this respect were the older observers of malarial blood (Virchow, Frerichs, and J. F. Meigs), and how near some of them came to anticipating Laveran's discovery (Kelsch and Joseph Jones).

The occurrence of flagellate bodies in three successive cases of acute intermittent seen this spring led me to look over my notes, and I was surprised to find how frequent flagellate bodies had been observed in my experience. Of the 12 cases carefully observed, in 7 acute cases they were found six times, and in 5 chronic cases twice or probably three times. The description of the bodies which follows is based on observations made in 4 cases of vernal intermittent, of from three days to one week's duration.

Corresponding to the stage at which they escape from the corpuscles (or are formed by budding, as described below), the free bodies vary in diameter from one-fourth of to quite that of a red blood-corpuscle. A large majority are slightly smaller than the latter. At rest, and when fresh, they are round, with positive but faint outlines, and always contain black or reddish-brown pigment, in short rods. The

pigment is usually gathered in a zone near the margin, the centre being clear and very bright and containing a dark globular body (nucleus?), as seen in Fig. 3. In some the nucleus is divided, or in dumb-

Fig. 3.



Flagellate body. The changes shown were observed within a period of ten minutes.

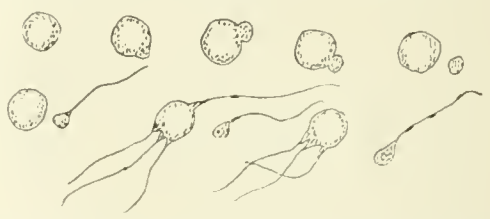
bell shape, or there are two or three clear spaces with pigment around them, as in the endoglobular forms (Fig. 2). In others the pigment is scattered over the optical surface, and in such it may be seen by focussing that the body is spherical, or spheroidal. In most of the bodies the pigment exhibits, at once, or soon after the preparation of a specimen, a peculiar motion. This was accurately described by Laveran, and quoted by Sternberg, but not mentioned, so far as I know, by other observers, who speak of the motion as "Brownian." Celli and Guarnieri have described a similar motion in bodies derived from crescentic forms.[1] Laveran's words are very vivid: "*Les grains pigmentés . . . . . sont animés de mouvements très vifs, comparables à ceux des particules solides qui se trouveraient dans un liquide en ébullition.*" That the motion is not Brownian may be seen by comparing the melanin granules in the bodies with others free in the plasma. It seems to depend on currents or contractions in the protoplasm of the bodies. The outlines of the bodies appear almost structureless, but at times the edges show an active undulation, when a membrane is apparently present. The undulation of the margin seems to be connected in some way with the formation of the filaments, and I have often been struck by the aptness of the comparison Richard drew between the process observed and the struggles of an animal. The edge waves violently, small projections are formed, pigment grains are ejected, and finally, in the words of Laveran, the filament shoots out. It may be apparently retracted again, but at last rhythmically oscillates or lashes to a length of twenty to thirty micromillimetres. Not all the filaments make so much commotion on their first appearance. Sometimes they appear on a side where there was little motion. It is usually said that filaments are never seen until from fifteen to twenty minutes after the preparation of a slide, but some observers have seen them earlier without a warm stage, and I have "focussed down" on a body with active filaments, with a surrounding temperature of 80° Fahr. Frequently I have seen the whole process end within fifteen minutes. The delicate structure of the filaments cannot easily be portrayed. They taper off rather abruptly from the bodies. Terminal knobs I have never seen, except those caused by pigment granules, but dilatations on the filaments have been rather frequent, and were always caused by movable pigment. In some cases the filaments appear to be tubular, as described by Laveran. I have often seen, as have others, the filaments, with or without pigment grains in them, tearing loose from the bodies, when they can be seen moving in a not very active manner, but often making wide excursions.

The production of filaments is not the only capability of the free bodies. Frequently a process of budding may be seen, the daughter-cells so formed having also a filament and dancing pigment.[1] I could trace no connection between the budding and the nuclear globules described.

In order to make clearer the characteristics of the bodies under consideration I reproduce sketches and notes made on a single one, in an observation lasting half an hour:

Fig. 4. Large round pigmented body; pigment marginal; edges undulating; intense motion of pig-

Fig. 4.



ment on side opposite eccentric nucleus (not shown in sketch); formation of a bud, in which pigment is intensely aggregated and dancing. The portion of the bud on the wall varies as much as 40 degrees; bud gradually constricted off; a filament four times as long as a red corpuscle formed on daughter-cell; mother continues undulating and pigment motion (the melanin rods) having an excursion of 20 degrees to 40 degrees around the periphery. Three filaments appear on mother-cell; opposite them a very long filament appears, strongly agitating adjacent blood corpuscles; daughter-cell approaches and indents a red corpuscle repeatedly, but does not enter it. Daughter-cell is larger, pear-shaped, pigment running up and down in filament.

When preparations containing free (flagellate) bodies are kept for some hours—though a half-hour may suffice—their dissolution may be seen. The edges become more vague, the body flattens out and

[1] Canalis mentions it in a recent work received after this paper was finished. Fortschritte der Med., 1890, No. 8.

[1] Celli and Guarnieri (loc. cit. p. 528) describe the formation of flagellate daughter-cells from atypical segmenting bodies, but do not mention the formation of filaments on the mother-cell. I have recently seen both, in bodies which correspond in other respects with those described by the authors.

finally remains as a shapeless, hyaline mass, with motionless pigment-granules scattered over it.

As already intimated, what I have said of the flagellate bodies is based on observations in the early stage of intermittent fever. Bodies similar in every respect, and accompanied with typical endoglobular forms and crescents, have been seen in protracted cases of severe intermittent; also in cases in which malarial infection could not easily be recognized without the microscope. In the latter they were the only forms, as in the following case:

M. R., laborer, living in the western part of Galveston, a swampy region. Admitted April 14, 1890, for diarrhœa. Had three chills six weeks ago, with intervals of one day. Took "Chill-cure." No more chills, but is peevish at times; spleen enlarged. In the blood numerous large, endoglobular, atypical bodies are found, together with many free bodies and flagellates. Kept on spirit of Mindererus for four days. The temperature rose to 99.8° F. from 2 to 4 o'clock P. M. daily. Patient expressed himself as feeling well. The bodies persisted as before; there were no typical forms. The diarrhœa having ceased spontaneously the patient left the hospital.

In a case of two months' duration seen last fall, which began as tertian but became quotidian, I found numerous free and flagellate bodies and crescents, but no endoglobular forms. The patient had been cinchonized for some time. Tonic treatment, with small doses of quinine, was carried out. There were no more chills. Flagellate bodies, and later the crescents, ceased to appear.

Other histories could be cited, but I think enough has been said to show not only the number, but the variety of cases in which the flagellate bodies occur, confirming in the latter respect what Councilman has said of the bodies.

As regards numbers, the flagellate bodies and free pigmented bodies seem to vary more in different cases than in the same case at different times (except under treatment). In some cases one only may be seen in a preparation. In one case every field had at least one, sometimes two or three. At times one can see a medium-size pair together. Not all of these free bodies had filaments, but some filaments could always be found, and no doubt many were overlooked in the brief time of the examination.

As to the origin of the bodies, my observations show beyond doubt that they are derived from certain endoglobular forms. From their occurrence in recent cases it would seem that they are simply varieties of the forms which carry on the typical process in malaria. But on the other hand, cases like the two described make it probable that they have an independent existence. To make this supposition stronger we must discover the unknown parts of the cycle of development—*i. e.*, the origin of the atypical endoglobular forms from the free bodies—as has been done for the typical bodies. In the first case here described I saw the nucleus of a free body break up into a number of oval globules, smaller than those of the tertian cyclical forms, but could not see their ultimate liberation. The most inviting solution of the question may possibly be found in the theory of Celli and Guarnieri[1] that the plasmodia can go into the reproductive phase at any stage of their development. It has occurred to me that perhaps the atypical and flagellate bodies are the results of such processes, and that they represent resting states of the organism, capable of existing independently, perhaps even of reproducing themselves, but also able, under favorable circumstances, of reproducing the typical growth of the parasite. Biology supports such a theory as much, I believe, as it does the theories which make them simply degenerative or post-mortem phenomena. In endeavoring to get some light on this question I thought of the action of drugs as perhaps giving some assistance. The effect of quinine on the parasites has long been known; *i. e.*, that it stops the development of the plasmodium, but has no effect on the crescentic bodies. In all the reports I have access to, large doses of quinine have been used. I endeavored to make the process less abrupt in the following case:

J. H. Acute quotidian intermittent: second chill. In the blood, developing plasmodia (rosettes) and flagellate bodies were found. He was given tincture of gentian for two days, the chills and condition of the blood continuing. Five grains of quinine given in solution three hours before the next expected chill prevented the paroxysm, but the blood contained bodies as before. That is, there were large, "ripe" plasmodia and free bodies with very active filaments. No rosettes. On the next day, after thirty-five grains of quinine had been given, the endoglobular forms were fewer, but the flagellates numerous and active. On the following day, with twenty grains of quinine, endoglobular bodies were not to be found, and of the few free bodies all were motionless, as was their pigment, and they developed no flagella. The patient was discharged at his own request and has not since reported.

In another case I tried a remedy which may prove a valuable addition to our list, viz.: nitrate of potassium, recommended by Dr. J. D. Hunter.[2] After my friend Dr. Hadra had told me of his success with this remedy in ague, I tried it, but, in order to observe the blood-changes more readily, gave it, not as advised by Hunter, in

[1] Loc. cit., p. 527.

[2] Virginia Medical Monthly, February, 1890.

large doses before and during the paroxysm, but in smaller doses, fifteen grains every three hours. The case was one of quotidian (double tertian) intermittent, of one week's duration, and had been treated by whiskey alone. I may add that the effect of saltpetre on a *potator's* stomach was much better than that of quinine. After beginning treatment there were no more chills, but the temperature rose on two successive days to 101.2° and 101.8° F. respectively. The manner of disappearance of the parasites was precisely similar to that in the other case; but as the patient was kept under observation ten days after the last chill the final and complete disappearance of the flagellate bodies could be followed.

In a third case quinine and saltpetre were used together, as follows: At the beginning of a chill (the second of a tertian) the patient took ten grains of quinine in capsules. The temperature rose to 100° F. Examined in the defervescence the blood showed organisms, endoglobular, free and flagellate. Saltpetre was given in the dose of thirty grains every three hours and the parasites disappeared in the same order as in the preceding cases.

These observations show a greater resistance to specific or antiperiodic remedies on the part of the flagellate bodies, and support the view I have advanced as to their nature—*i. e.*, as resting forms. A temporary cessation of intermittent fever prevents me from carrying these observations further, so that for confirmation as well as for learning additional details regarding the atypical bodies we must await future investigations. It is in the hope that others may take up the matter that I bring forward these few observations.

My observations on the crescentic bodies, though rather numerous, are all imperfect from the fact that I could not observe my cases in their natural condition for a long enough period. Observers are unanimous in considering these bodies the constant parasites of the chronic irregular forms of malaria, and of malarial cachexia, but as to their origin and development and relation to the other forms there is still great difference of opinion. Most recent investigators ascribe to these bodies an endoglobular development, but the accounts of various authors differ radically. Golgi, who looks on the endoglobular origin as undemonstrated thinks they represent a later stage in the development of the flagellate bodies. I have not yet seen his latest contribution on the subject.

I have never seen a crescent in a red blood-corpuscle, although in some of my cases crescents were so numerous that six or seven could be seen in a single field. Still, I am inclined to believe in the endoglobular development of these forms, on account of the numbers in which they occur, the destruction of blood corpuscles in those cases, and the difficulty of accounting in any other way for the melanin they contain. The most interesting explanation of the origin of the crescents is that suggested by Grassi and Feletti (p. 434), viz., that it takes place in the bone-marrow. This explains why undeveloped crescents are so seldom found in blood from the finger, and receives support from observations of Danilewsky on certain parasites of reptiles, probably belonging to the same class as those of malaria.

Crescentic bodies are seldom found in recent cases. The following history shows the most rapid development I have yet seen.

October, 1889, a man who had never before had malaria lived for four weeks in one of the most noted ague localities in Texas. A week after his arrival a quotidian intermittent became manifest and soon the paroxysms were doubled, one in the day and one at night. Quinine was taken to cinchonization during the first week; after that not at all. Examined three weeks after the first chill. His blood then showed many crescents, but no endoglobular or flagellate forms. The blood corpuscles numbered 2,335,000 per c.mm.

Under the energetic use of quinine, arsenic, strychnine and iron there was steady improvement and there were no more chills. Crescents gradually disappeared.

The changes the crescents undergo have often been described and need not be repeated here. That they are cadaveric I have no doubt. The production of filaments on them, however, I have never seen, although I have looked for it long and frequently. In all cases where filamentous bodies were found with crescents, the flagella could be seen to develop only on the bodies already described.

A word in regard to an important subject, namely phagocytosis. I have endeavored to study this in malarial blood, but the results were disappointing. I have often seen the atypical bodies enclosed, while still active, in leucocytes (large polynuclear and eosinophile), and have followed their gradual disintegration. But considering the number of free bodies and leucocytes encountered, the process, on the whole, is infrequent, and "pigmented leucocytes" do not figure so largely in our notes on malarial blood as before the parasites were known (James, p. 270).

As said at the outset, it is not the object of this paper to consider the whole aspect of the pathology of malaria, and I have purposely avoided discussing the biological and etiological relations of the malarial parasite.

As to the former I can add nothing to the latest conclusions of those who have given most thought to the subject. The lowest classes of animal organisms, to which the hæmatozoa malariæ are evidently related, are so imperfectly understood that at present

we learn but little from them. The investigation of malarial blood by biologists with special training must throw a great deal of light on that subject. Though culture methods and ordinary inoculations are not available much can be done, with no danger and but slight discomfort, by inoculations in man.

As regards etiology, while the strict methods of bacteriology cannot be applied to malaria, proof as to the causal relation is stronger, it may be remarked, than it is for some parasites whose pathogenic nature is not questioned, *e. g.*, the trichina spiralis. Inoculations by many observers have shown that the virus of malaria exists in and is transmissible by the blood. In the latter we find the organisms, whose cyclical, combined with irregular, polymorphous development furnishes so perfectly what clinical pathology requires of the germ of malaria. Added to this we have the action of quinine, which, specific as it is for some forms of the disease, is so probably only by virtue of its power over amœboid organisms in general.

The value of the organisms in diagnosis has been emphasized by all who have tested the matter. The use of the microscope in clearing up the nature of a host of vague complaints, called by both profession and laity "malarial," and in limiting the application of that term to the proper class of diseases, should be general.

Not only in diagnosis is the microscope of practical value in malarial diseases, for with its assistance specific remedies can be used more rationally than heretofore, and with a certainty not otherwise possible.

CLINICAL MEMORANDA.

SURGICAL.

Mucous Polypi of the Bladder in a Child. Suprapubic Operation. Death on the 23d Day.—The following case is reported somewhat in detail; first, because cases of vesical tumor are by no means common; and, second, that it may add to the data available in forming a prognosis in such cases, although some doubt as to the exact cause of death makes the case one of uncertain value in determining the prognosis of future operations.

The case is as follows: March 11, 1890, I saw for the first time R. B., aged four and a half years. The boy was considerably emaciated, but there was no satisfactory evidence of any disease other than that of the bladder. The symptoms dated back eight months, and had been gradually increasing in severity. At the date above mentioned, there was frequent micturition, with much vesical tenesmus and pain; some dribbling of urine (urine was never bloody); prepuce elongated from frequent handling. Micturition was distinctly easier when the body was in a horizontal position. Microscopical examination of urine revealed nothing more than evidences of cystitis. There were the ordinary symptoms of stone, but with more than the ordinary amount of pain and tenesmus. The boy was accordingly examined for stone on two different days and under chloroform; the instruments used were a small, ordinary urethral sound, and a small, flexible, metallic olive-tipped urethral bougie. The results of these examinations were not satisfactory. With a finger in the rectum, the bladder felt thick and boggy even after the urine had been drawn off by a catheter. The sound could be felt through the base of the bladder, and once upon entering there was a faint suspicion of a "click." At another place there was a suspicion of a grating sensation that was also suggestive of a calculus. These suspicions, however, did not warrant a cutting operation—certainly not cutting for *stone*. The only fact that might have been suggestive of the true condition of affairs was that the amount of urine that could be drawn off with a catheter did not correspond with the suprapubic percussion dulness, which persisted in a considerable degree after withdrawal of the urine. Another fact already mentioned, and particularly noticed by but one of several authorities consulted upon the subject, was the *inordinate* vesical tenesmus. Although no blood appeared during or after the two examinations referred to, the pain and tenesmus were increased thereby, and an operation was decided upon as the best means of curing the cystitis and relieving the tenesmus.

A suprapubic cystotomy was therefore made under some disadvantages. Owing to circumstances beyond the control of the operator, the child could not be moved to a hospital; the house was small and the surroundings decidedly unattractive from a surgeon's point of view. No rectal distention was used, the bladder being moderately distended and irrigated at the same time by a stream of warm, boiled water from a fountain syringe at an elevation of three feet above the bladder. A median incision two inches long and just above the symphysis gave access to the bladder-wall, which was incised between two supporting tenacula. The peritoneum was not seen. The incision was made large enough to admit a finger, and the bladder was found completely filled with pedunculated mucous polypi varying in size from one-eighth to one inch in diameter and variously attached to the base of the bladder, but grouped more closely about the vesical neck. These were carefully removed with the finger-nail and forceps, and when removed half filled a one-ounce quinine bottle. The hæmorrhage

was unimportant. The bladder-wall was not sutured. Two or three deep sutures closed the abdominal wound about a Trendelenburg drainage-tube—no perineal drainage, or catheter in the urethra. The pain and tenesmus were entirely relieved by the operation, and the child's general condition seemed much improved. The wound was dressed daily, and the drainage-tube removed on the sixth day. The temperature was normal until the seventeenth day, when there was slight fever and some looseness of the bowels. The wound looked healthy, and the cause of the disturbance evidently was one or two recent errors in the management of his diet. On the eighteenth day there were two general convulsions, with loss of consciousness, lasting two or three minutes; looseness of the bowels continued, with pronounced though not excessive tympanites. On the two following days there was some general improvement. There were no more convulsions and no higher temperature, but on the twenty-third day the patient died with no more marked symptoms than those above described.

OBSTETRICAL.

A Case of Placenta Prævia; Death.—The following case is that of an Italian woman aged thirty-four, who had had three children, all of which are living. The labors were easy. To this case my friend Dr. Cheston, of Chestnut Hill, called me in. The woman, according to our informant, had been bleeding so profusely for fifteen hours that the bedclothes and surroundings were soaked. On arrival we found a very pale, though fairly well-nourished woman. Her pulse was weak, and respiration hurried. She was not bleeding at this time. We were informed that she was in the seventh month of pregnancy. On vaginal examination the os was found the size of a half-dollar, and on introducing the examining finger, all antiseptic precautions being carefully observed, the placenta was found firmly adherent around and across the os, and bleeding when touched. The woman being very weak from the excessive loss of blood, and not bleeding at this time, version and delivery were delayed. As she had some bearing-down pains, one drachm of ergot every two hours was ordered, and the vagina was tamponed.

The foot of the bed was raised. Hot black coffee, and half an ounce of whiskey with tincture of digitalis were given also, every two hours.

In the evening, about eight hours later, we found her bleeding, but in a somewhat better condition. Having been allowed to get up out of bed to bear down, she had forced out the tampon. She had vomited her ergot and stimulants.

We decided to perform version and delivery by the breech. External version was done, the os still about the size of a half-dollar, and the feet were brought down. The woman was given her coffee and milk, and hypodermic stimulation was resorted to, but the pulse was failing. The breech being delivered, the arms were extracted, but great difficulty was experienced in delivering the head, and after some effort the forceps were applied. After the child was delivered the uterus commenced to contract under the action of external abdominal stimulation. The placenta was apparently normal. The child, rather large, was born dead. The mother never reacted from the profound collapse, and died an hour after labor.

Resident Physician, Germantown Hospital.

MEDICAL PROGRESS.

Treatment of Granular Lids with Strong Solutions of Bichloride of Mercury.—In the *University Medical Magazine* for July, 1890, is the following report from the hospital service of Dr. G. E. de Schweinitz:

The favorable reports which from time to time have appeared in regard to the value of strong solutions of bichloride of mercury in the treatment of granular lids have led to an extensive trial of this remedy in the eye wards of the Philadelphia Hospital. The method adopted is as follows: Every alternate day the everted lids are carefully touched with a solution of bichloride of mercury, 1 : 300 or 1 : 120, according to the size of the granulations, while three times a day the conjunctival cul-de-sac is irrigated with a warm solution of the same drug, 1 : 7000. No other medicine is employed. The results have been almost uniformly favorable. In no single instance has the disease been aggravated; in a few it has apparently undergone no modification, while in the vast majority, after four or five applications of the character described, there has been increased comfort, lessening in the size of the granulations, dissipation of the discharge, and not infrequently amelioration of pannus, if this was present. Perhaps the strongest testimony in favor of this application is that given by most of the patients themselves, all of the chronic cases having, either in this institution or elsewhere, had all manner of local astringents applied to their everted lids. Their testimony is practically unanimous that this has given the greatest comfort. It is a painful application, and in sensitive patients, as has been recommended, the eyes may be cocainized. In most of the instances, however, this precaution has not been deemed necessary. These observations are based upon the experience of about thirty cases.

The Pathogenesis of Yellow Fever.—Drs. Finlay and Delgado (*Lancet*, June 21, 1890), who have for some time been engaged in investigating the bacteriology and pathology of yellow fever in Cuba, recently read a paper on the subject before the Havana Academy of Sciences, in which they detailed their experiments and discussed their significance, with special reference to the researches of Dr. Sternberg. They say that Sternberg's micrococcus Finlayensis has been found by Dr. Kinyoun on the skin of patients suffering from malarial fever in localities where yellow fever does not occur, and that it is, therefore, impossible that this microörganism can bear any relation whatever to the causation of yellow fever. The micrococcus tetragenus versatilis has been found in the serous fluid of blisters on yellow fever patients in spite of the most careful disinfection of the skin, in one-half of the cases examined, and in three-eighths of the specimens on which observations were made. This micrococcus was found in the blister serum of persons resident in Havana and acclimatized, in two out of seven cases examined, and in three-thirteenths of the speci-

mens taken, but only in cases where the disinfection of the skin had been omitted, or in which it had been but imperfectly performed. Nothing of the sort was found in any of the eight specimens taken from four persons whose skin had been as thoroughly disinfected as that of the cases of yellow fever.

The Dangers of Tonsillotomy.—Removal of the tonsils by the bistoury or guillotine is a popular operation in England and America. The French are less partial to it, and MM. Quénu and Lucas-Championnière have recently dwelt on its dangers at the Paris Société de Chirurgie. The latter surgeon referred to two cases in Broca's practice where profuse hæmorrhage followed removal of the tonsils. In one of these instances the patient, a medical student, died almost immediately after one tonsil was cut, so violent and uncontrollable was the bleeding. In a case in M. Lucas-Championnière's own experience the patient, a middle-aged man, had enlarged tonsils, quite free from inflammation, and he was not suffering from any morbid condition likely to prevent the natural arrest of hæmorrhage. On removal of one tonsil hæmorrhage took place, and could not be checked until after two hours of digital pressure with a tampon soaked in ergotine. M. Quénu always uses the galvano-cautery three or four times, at intervals of a fortnight, and atrophy of the tonsil always follows. MM. Marc Sée and Chauvel do not dread the knife. There can be no doubt that hypertrophy of the tonsils require active treatment, especially in youth; and the evil consequences of neglect are well known. In the majority of cases the risk of dangerous hæmorrhage is very slight; but the possibility of its occurrence should always be borne in mind, and the use of ice or of a styptic gargle should be enforced as a measure or precaution immediately after the operation. —*British Medical Journal*, June 21, 1890.

Prescription for Exophthalmic Goitre.—According to the *Weekly Medical Review*, Dr. A. F. Watkins recommends the following prescription in the treatment of exophthalmic goitre:

℞.—Picrotoxin . . . . $\frac{1}{30}$ grain.
Aqueous extract of ergot . 2½ grains.

Make into a pill. One pill should be taken three times daily.

Aseptic Wound Treatment.—Bloch, of Norway, deprecates the use of corrosive sublimate as an antiseptic in surgical practice, and believes that with proper precautions as good results can be obtained without this agent as with it. The author's usual method of procedure is as follows: The region to be operated on is cleansed with soap and water, ether, and carbolized water (3 per cent.); the instruments are sterilized by exposure to steam, and then laid in carbolic solution (3 per cent.). At the end of the operation the wound is irrigated with carbolic solution of the same strength (sometimes it is first swabbed with chloride of zinc, 10 per cent.); all ligatures and sutures are of catgut, prepared by steeping first for forty-eight hours in 5 per cent. watery, then in 5 per cent. alcoholic, solution of carbolic acid. The author has discarded Schede's sublimated catgut, culture experiments having shown it to be not invariably sterile. Drainage-tubes (red rubber) are kept in 3 per cent. carbolic solution. Two layers of sterilized gauze are interposed between the absorbent dressing and the wound to keep the cotton-wool from sticking to the stitches. The drainage-tubes are removed on the third, fourth, or fifth day, and the dressing then applied remains on for two or three weeks.

After summing up the results of twenty-nine cases managed in this manner, the author is able to say that wounds treated with sterilized cotton-wool heal in an ideal manner. Nevertheless, on examining the secretions of the wounds, as was done in every case, there were found microbes even in the "aseptic" clots from the drainage-tubes withdrawn on the third, fourth, and fifth days. None the less he is able to record perfect union, by first intention, without any suppuration whatever.

The microbes found were monococci, diplococci, and staphylococci. Cultures usually showed these to be staphylococcus albus; rarely staphylococcus pyogenes aureus or bacilli were found.

Cases treated with a layer of iodoform gauze next the wound give equally good results. Here, too, there were microbes in the clots; from one case, which healed ideally, there was obtained the staphylococcus pyogenes aureus.

With carbolized gauze next the wound the results were the same: the wounds healed in perfect manner, but microbes were present. In only two out of seventeen cases could they not be found. They probably lodge in the epidermis, and are practically ineradicable from it; and it must be supposed that their development is inhibited by the antiseptics applied to the wound during and after the operation.

Conclusions.—1. Large operation wounds may heal as perfectly, in a clinical sense, when dressed with sterilized materials not containing any antiseptic agents as when treated with antiseptic dressings.

2. Large aseptic operation wounds, dressed simply with sterilized cotton-wool, heal generally by first intention.

3. The secretions of wounds, healing without any suppuration whatever, contain microbes, as a rule, whether the dressing contains bactericide agents, or consists simply of sterilized materials.

4. Wounds containing microbes (abscesses, etc.), dressed simply with sterilized cotton-wool, may pursue a course identical with that which they would have pursued had they been treated with antiseptic dressings.

The logical issue of the investigation would be the recommendation of sterilized cotton-wool as the best form of dressing. For private operations, where two intelligent persons can divide the work between them, it is available with full security. But in large hospitals, where the carrying out of details is divided among a number of persons, a certain security is gained by the addition of an antiseptic agent.

For this reason the author recommends the treatment of wounds by carbolic acid, with the modification that the outer layer of the dressing shall be not of macintosh, but of sterilized non-absorbent cotton-wool.—*Glasgow Medical Journal*, June, 1890.

The Dangers of Constipation in Children.—In a lecture recently delivered before the Paris Hospital for Sick

Children, DR. JULES SIMON (*Journal de Médecine et de Chirurgie*, May, 1890) called attention to the fact that while diarrhœa occurring in children is the object of the most extreme solicitude both on the part of parents and of physicians, constipation, which possesses almost as great danger, is almost entirely neglected. He called attention to the case of a girl, fifteen years of age, who was brought into the hospital suffering from extreme abdominal pain, caused by a fall upon the abdomen, and followed by an abscess in the abdominal walls. The symptoms, however, rapidly increased in intensity, and were followed by vomiting and diarrhœa, and the patient died at the end of a few days. At the autopsy there was noted general peritonitis, with a perforation of the cæcum, surrounded by an old purulent deposit in this region. There was thus typhlitis, followed by perforation, which led to the formation of an encysted abscess in the pelvis, and only as the result of injury was general peritonitis produced. Dr. Simon believes, from the nature of the lesion observed, that the inflammation and the perforation were the consequences of marked constipation, leading to a rapidly fatal termination by traumatism. He believes that cases similar to the one reported are much more common than is ordinarily supposed, and he thinks that in many cases faulty development and numerous digestive disturbances are attributable to more or less obstinate constipation. Indeed, even in some cases death itself may follow either through the production of typhlitis and the perforation of the cæcum, as in the present case, or from intestinal obstruction. Dr. Simon stated that in another case he had seen death produced by a fæcal tumor the size of a child's head. In such cases the author has frequently obtained satisfactory results from electricity, but when the obstruction has been overcome by this means, it must be recognized that the patients are constantly exposed to a return of a similar state of affairs; for the intestinal tube, after such great distention, becomes the seat of structural modifications, and is almost incapable of resuming its normal condition. There is thus a practical point to be observed, whose neglect may be followed by the most serious complications, and in examination for the cause of obscure infantile troubles the occurrence of constipation as a possible factor should never be overlooked, especially as constipation may be actually obscured by an apparent diarrhœa.—*Therapeutic Gazette*, June, 1890.

Condensed Milk as an Infant-food.—DR. LOUIS STARR considers condensed milk a good food for infants while travelling, or under circumstances in which good cow's milk cannot be procured. If possible, he gives it in the following mixture:

Cream	1 tablespoonful.
Condensed milk . .	2 tablespoonfuls.
Water	11 "
Mellin's food . . .	1 tablespoonful.

In preparing this, the water should be heated to the boiling point, adding first the Mellin's food, then the condensed milk, stirring constantly until the solution is complete. After the mixture has slightly cooled, the cream is added. This amount is sufficient for one meal for a child of eight months.—*Annals of Gynæcology and Pædiatry*, June, 1890.

Ointment for Chapped Hands.—According to the *Journal of Cutaneous and Genito-urinary Diseases*, the following is an excellent application for chapped hands: Dissolve one part of boric acid in twenty-four parts of glycerin; add to this solution five parts of anhydrous lanolin and seventy parts of vaseline. The mixture may be colored and perfumed.

A Plaster-of-Paris Splint for the Treatment of Fractures of the Leg.—DR. A. G. R. FOULERTON describes the following method of applying plaster dressings to fractures of the leg (*Lancet*, June 28, 1890):

In the case of a fracture, say, at the junction of the middle and lowest thirds of the leg, three measurements are taken: (1) The length of the limb from a point an inch and a half above the knee to the sole of the foot; (2) the circumference of the thigh at the level of about an inch and a half above the knee; (3) the length of the foot from the heel to the ball of the big toe. An oblong piece of shrunken flannel or old blanket is then cut to such dimensions that it is in one direction an inch and a quarter longer than measurement 1, in the other an inch and a half less than twice the measurement 2. The limb is laid on the flannel, which is then held up by its edges, supporting the leg as in a sling. Next, the flannel is tacked together with needle and thread close to the limb, down the front of the leg, along the sole, and then along the dorsum of the foot. It is better to sew the flannel in the order given, along the sole first and along the dorsum afterward, because by doing so the foot will be held by the flannel in the position in which it should be—at a right angle with the axis of the limb. The leg is thus closely encased in flannel, while along the front of the leg and the dorsum and sole of the foot a double free edge of flannel is left beyond the seam. These free edges along the dorsum of the foot, as high as the ankle, and along the sole, are trimmed off close to the seam. There now remain two considerable wings of flannel extending down the front of the leg as far as the ankle. Each wing, when turned back from the middle line in front, will reach to within about half an inch of the middle line behind. These wings are then trimmed from below upward, so as to shape them to the form of the leg. Two side splints with rectangular foot-pieces are then cut out of flannel, so that each piece, when applied to the limb, shall reach to within about a quarter of an inch of the middle lines in front and behind. Care must be taken that the anterior edge of each side-piece is quite straight; the posterior edge may be shaped so as to allow for the swelling of the calf muscles. Traction is then applied to the limb, and these side-pieces, having been thoroughly saturated with plaster-of-Paris mixture, are placed over the flannel casing, one on each side of the leg. The wings of flannel are then quickly folded back, each over its respective side-piece, and smoothed down. Plaster-of-Paris is then rubbed well into the outer surface of the two flannel wings, avoiding, however, a border about a quarter of an inch wide down the front of the leg on either side of the seam. The perfect adaptation of the splint to the limb may then be secured by applying a thin muslin roller-bandage over the whole from the toes upward. After ten minutes the muslin bandage is unrolled, and the splint is then finished. The plaster will probably be quite dry in the course of an hour.

THE RELATION OF THE HOSPITAL PHYSICIAN TO THE HOSPITAL SURGEON.

THE existing unwritten, yet inflexible, laws governing the actions of the members of a hospital staff in regard to one another are becoming, at the present time, so unsuited to the demands made by the rapid progress and subdivisions of medical science as to require serious innovations if the benefit of patients is to be considered as a more important matter than the preservation of professional ethics. Our attention is called to this growing evil by the generally acknowledged fact that the various branches of medical science are each becoming so vast in their scope and minute in their individual technique that no one is capable of carrying out successfully all of the operations or therapeutical measures which patients of every class may present. We fear that some surgeons and physicians still believe themselves able to treat all the ills to which man is subject, without calling in the aid of any of their brethren, and that there are others who, from pecuniary motives alone, neglect to send a patient to a more experienced friend because they will lose the case. This lack of humanity and abuse of professional confidence are not, however, the evils at which this editorial is aimed. What we complain of is the lack of recognition on the part of the boards of managers of hospitals of the fact that the staff should consist of a body of men not all general surgeons or physicians, but some of them specialists in the important parts of medicine and surgery. Either this fact must be recognized, or the individual members should be allowed to call into their wards, in consultation or for operation, friends who in their opinion are qualified to assist or take entire charge of a given case. At present this is considered a professional impossibility, yet every one who has occupied a position on a hospital staff must have experienced the difficulties of referring a patient to the care of his colleague, knowing when he did so that while his friend was an accomplished physician or surgeon, he was in reality utterly without adequate training for that particular emergency.

As an instance of this we may cite a case which was recently brought to our notice, in which a woman suffering from peritonitis of a frequently recurring type came under the care of a physician who had charge of a ward in a large hospital. The history of gonorrhœa and the entire atmosphere of the case showed it to be one demanding operative interference of a most skilled and experienced character, an experience confessedly lacking in the eminent surgeon on service at the same institution during the course of the case. Under these circumstances this surgeon would have been bound to operate if called on, since he could not refuse to perform an act so plainly indicated, nor could he confess his inability to do so through ignorance. There was, therefore, but one path left for the physician in charge; namely, to wait until the inflammation remitted in its violence, and then hurriedly to discharge the patient with a recommendation to call on a surgeon qualified to relieve her without exposing her life to unnecessary risk. In the case before us the surgeon attached to the hospital had enough conceit to believe himself capable of operating on anything, but the subsequent history of the case proved that only the most dexterous and experienced of men could have possibly saved the woman's life, because of the extensive abdominal lesions produced by her disease.

If the physician had referred his case to his colleague with his knowledge of his colleague's inability to treat it, the one would have been but an accomplice to a professional murder, and the other a man who, by the force of existing laws and his conceit, must forever have the awful responsibility of the loss of a human life resting upon his shoulders. In this

instance the remittance of the disease permitted the physician to do the best he could for his case, and he practically advised her to flee from the hands of his colleague; but had no remittance in the disease taken place, he would have had to be content with letting her die on his hands, or of sending her to her death in the surgical wards. We cannot clearly see our way toward remedying this evil, but the evil exists, and as such should be remedied, and if any of the readers of THE MEDICAL NEWS can recommend a plan we shall be glad to hear from them. The mere appointment of specialists does not entirely avert the danger, since the individual so appointed may not entirely command the professional confidence of his colleagues in every case which appears. No practitioner sends all his private cases to one surgeon or physician, but selects for each case the professional brother best qualified to take care of the diseased process suffered from.

CORRESPONDENCE.

MILK INSPECTION IN CINCINNATI.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of June 21st your Cincinnati correspondent indulges in some statements in regard to the dairies and milk-supply of this city, which are not only sensational and untruthful, but reflect very unfavorably upon all who have heretofore held the position of Health Officer. No such state of affairs as is depicted by your correspondent has existed for years, if ever, in this city. All of Dr. Prendergast's predecessors have paid much attention to the dairies and milk-supply, and very few cities in the country have had better milk than this has had.

For the last four years the office of milk inspector has been filled by an honest physician, who was very attentive to his duties, and was well versed in chemical analysis, and who had as assistants competent and trustworthy inspectors of dairies; and their weekly reports to the Health Office showed that their duties were not neglected.

If your journal were read only by Cincinnati subscribers no reply to your correspondent would be necessary; but to those who do not know the absurdity of his letter, I desire to say that his statements that "the dairies were in an appalling condition," that "in some, the cows stood up to the knees in filth," and that "many of them had not been liberated from their stalls for more than a year," are utterly devoid of truth, and that his letter is but an attempt to write into notoriety a set of newly appointed men who were absolutely ignorant of the duties they were expected to perform.

Yours respectfully,

BYRON STANTON, M.D.,
Ex-Health Officer of Cincinnati.

To the above letter our Cincinnati correspondent replies as follows:

To the Editor of THE MEDICAL NEWS,

SIR: In the letter which I had the honor of contributing to THE MEDICAL NEWS of June 21st, it was my aim to give you the opinions of the local medical profession, and not my own ideas; and I was particularly careful to consult the best available authorities with reference to the truth of every statement before its publication. When, therefore, Dr. Stanton takes exception to my letter, he flatly denies, not merely the veracity of a newsmonger, but the official action of the Cincinnati Academy of Medicine, of which he is a member, the verdicts of the daily press, compiled at great length and with many illustrations, not from the reports of the Health Office, but from personal investigation by reporters, and, I might add, from the confessions of dairymen who made no denials but pleaded inability to obey the law profitably. What there was, therefore, of the "sensational" in my letter was of the character which is inherent in the description of a dire calamity of large proportions, though it be the slaughter of innocent babes through the ignorance and carelessness of milk-producers Through personal regard for Dr. Stanton and the esteemed physician who was associated with him as milk-inspector during his term of office, as well as at the request of the present Health Officer when interviewed, I not only refrained from criticism or censure of previous officers, but distinctly stated in the letter referred to, that "In the revelations which have been made there has been no attempt to reflect unfavorably on the official career of previous health officers, and no such reflection should be made. The fault lies not with those who have occupied the office . . . but with the city government." I heartily agree with Dr. Stanton as to the official honesty and professional ability of himself and associates in office, and have still no desire to criticise them.

But, when the ex-health officer selects from my letter the statements that the "dairies were in an appalling condition," that "in some the cows stood up to the knees in filth," and that "many of them had not been liberated from their stalls for more than a year," and asserts that they are utterly devoid of truth, I most respectfully but emphatically deny and refute his statement. On the evening of May 12th, the Cincinnati Academy of Medicine unanimously adopted a resolution of which the following is a part:

"*Resolved*, That we have witnessed with much surprise and alarm the exposures recently made by the Health Department of our city under the direction of Health Officer Prendergast, of the appallingly unsanitary condition of a large number of the dairies which supply us with milk, but we fully endorse the efforts of the Department to correct the existing evils . . . that we tender to the Health Officer our earnest support, and urge him to continue his efforts to increase the efficiency of the Department in the same energetic and fearless manner as he has begun."

"Filth to the knees" was the condition described in the daily press, and I am informed that it is correct. It might have been an inch or two less deep, if the Jersey cow was taken as the standard of measurement, but the fact remains that the filth was there, and that the cows stood in it. Even worse, an eye-witness informs me that in at least one instance the cow's udder was so besmeared that this same filth dropped from the fingers

of the milker into the pail, and remained there until the milk was strained.

The *Cincinnati Lancet-Clinic*, May 17, 1890, says editorially:

"From time out of mind Cincinnati has been greatly cursed with a stock of dairies that have had a place and habitation within the city precincts, where the cows were almost wholly fed on distillery slops and starch grains. As if this were not bad enough, the poor unfortunate animals are, month after month, confined within the stables, and often standing in their own filth; while, to make the condition as bad as possible, the frame sides of the sheds are, in the fall, as hermetically sealed as possible with the dung of the cattle."

Now, whom are we to believe? If the letter of June 21st was so "utterly devoid of truth," what of these other statements? and if these were false why did not the injured ex-health officer immediately cry aloud and at home? Why did he select for refutation (?) a letter in which his official career was vindicated in preference to those in which he had been less kindly dealt with? His statement, that no reply would be necessary if read only by Cincinnati subscribers, is as aqueous as any of our milk.

If the letter of June 21st was "intended to write into notoricty a set of newly appointed men," it came too late, when prompt and energetic devotion to duty had already made them "notorious." And if these neophytes were "utterly ignorant of the duties they were expected to perform" (can he refer to obligations to the dairymen?), then may we thank the kind Providence that sent us men thus ignorant, Democrats though they be!

MODIFIED CHEYNE-STOKES RESPIRATION.

To the Editor of THE MEDICAL NEWS:

SIR: The article in THE MEDICAL NEWS of May 31, 1890, by Dr. Norton Downes, on "Cheyne-Stokes Respiration," brings to mind a case that I met with last autumn.

A boy, between three and four years of age, had had a severe attack of diphtheria, but had recovered from its immediate effects. The membrane had disappeared from his throat and nostrils, and his physician thought that there would be no further obstacle to recovery. The child, however, continued debilitated, and seemed unable to regain his strength. Some days later I was called in. The parents had become alarmed at a peculiarity of the breathing that had developed. This peculiarity was like that of the cases referred to by Dr. Downes as having been reported by Dr. William O'Neil, viz., deep inspirations, with long intervals of rest. This was particularly noticeable when the child was sleeping, either in the night or day. Sometimes there was very little noticeable in his respiration except an occasional long breath, but when he fell asleep the peculiar respiration would occur, sometimes to such an extent as to alarm the parents and friends. At no time was there the quick shallow respiration, followed by the period of apnœa, so marked in well-developed cases of Cheyne-Stokes respiration. Examination showed that his heart was weak but regular in action, the pulsations ranging from 110 to 120 per minute. Throughout the case there was no cyanosis or rise of temperature. On testing the urine, which was diminished in quantity, I found abundance of albumin, but at no time was there any dropsy, other than slight puffiness about the eyelids and lips. Constipation was present, and the complexion was of that clayey, unhealthy appearance, not uncommon after diphtheria, and always present in anæmic and dropsical patients. Some days after my first visit, paralysis of the palate began, and continued until it was almost complete. In spite of the fact that the condition of the kidneys improved, as shown by urinary tests, and by the improvement in the respiration, the child continued to grow weaker, and while there was no actual paralysis of the lower limbs, the patient was unable to walk. After careful treatment for about six weeks, I regarded him as convalescent, and he finally completely recovered.

The points of peculiar interest in this case are, that the difficulty in respiration increased during sleep, yet at no time was it sufficient to keep him awake; and that there was no cyanosis. My explanations of these peculiarities is that the case was one of uræmic poisoning, and the centres of respiration were benumbed by the poison circulating in the blood, yet not sufficiently so to prevent the child's recognizing the want of air when awake.

Now, during sleep the centres failed to act, except when the *non-aërated* blood roused them to action, and when the need of oxygen was felt. By the expression "*non-aërated* blood," I mean blood deprived of a certain amount of oxygen, and carrying enough carbonic acid or uræmic poison, or both, to overcome that state of inactivity, and to cause the respiratory centres to respond. In thinking over the matter of cyanosis, I have concluded that the deep, full inspirations at intervals, really furnished almost as much air in a given time as is normally furnished, and that while the respiratory centres were so influenced as to cause irregular breathing, yet they were sufficiently active to respond before the lack of air was so great as to cause cyanosis.

W. R. CUSHING, M.D.

DUBLIN, VA.

ABSORPTION OF BONE-SPLINTERS.

To the Editor of THE MEDICAL NEWS,

SIR: The question as to the extent to which splinters of bone detached from the periosteum may be absorbed is an interesting one. It has seemed to me that the possibility of absorption might be greatly increased by appropriate measures. The cases that have come under my observation in which this condition was supposed to exist were not verified by post-mortem examination, and it is on this account that I take the liberty of suggesting the following points as perhaps worthy of the attention of those who may have greater opportunities for their verification.

It is evident that even slight irritation due to motion of the fragments of the delicate granulation tissue surrounding splintered bone tends to produce swelling and stasis, which prevent absorption. If in the effort to prevent such motion bandages are drawn too tightly, absorption is interfered with. I have seen two instances, at least, in which, so far as could be judged from the symptoms, a long bone had been

splintered so as apparently to separate fragments from the source of their periosteal blood-supply. In both, however, absorption seemed to have taken place and to have become complete without suppuration, at the end of several months. It was thought that this result was due, in part at least, to the treatment adopted, which consisted in the prolonged application of the ideal elastic pressure secured by means of splints which had been upholstered with curled hair. By means of such splints it is possible to hold the parts immovable with comparatively gentle pressure and without any tendency to strangulation and consequent pain and swelling. Moreover, they are light, cool, and comfortable. Certainly, in the difficult and tedious cases mentioned, they contributed to the favorable result, whatever may have been the precise pathological condition.

A Successful Cæsarean Section by Candle-light.—D. F. Albert Mouillot, in the *British Medical Journal*, June 28, 1890, reports a successful case of Cæsarean section in a woman four feet eleven inches in height. The distance between the anterior superior spinous processes was only eight inches. The operation was done by candle-light in a peasant's house, and with no other instruments than those of a pocket-case. Dr. Mouillot attributes the recovery to the fact that the woman was not exhausted before the operation, and that strong uterine contractions followed.

A Fatal Epidemic of Whooping-cough.—The *British Medical Journal* states that the mortality from the epidemic of whooping-cough now pevailing in Aberdeen, Scotland, is exceptionally high. During the month of May one case in every eight proved fatal.

Increase of Insanity in England and Germany.—It is computed that there is an annual increase of 300 to 400 lunatics in London. A new asylum for the accommodation of 2000 patients has been begun, and will be finished in about two years. At the present rate of increase of lunacy in that city a new asylum will be required every five years. The population of the city is stated to increase about 80,000 per annum, so that a large lunacy increase is explicable.

It is stated that in the German Empire during the past five years there has been an increase of 25 per cent. in the number of cases of insanity, against an increase of 3.5 per cent. in the population.

Artesian Water-supply at Memphis.—The new artesian water-supply of Memphis, Tenn., is probably as perfect as that of any city in this country. According to the *Bulletin of the Tennessee State Board of Health*, the supply is practically inexhaustible, such is the capacity of the water-bearing sand, and it is estimated that, however great the amount of water used, no impression can be made on the subterranean river of supply. It is assured that clear water, free from admixture with river water or surface drainage, can always be obtained. This is rendered probable by the fact that there is an upward pressure from the wells to a point that is higher than the high-water mark of the Mississippi River. The water, as delivered from the wells, is sparkling and transparent, and is unaffected by rains or by turbidity of superficial streams. Its fountain-head must be at a distance of many miles. The system for gathering, storing, and distributing, has been constructed in an unique and admirable manner, and, from a hygienic point of view, its introduction is a blessing to all concerned, and the system will be a model to other cities in the valley of the Mississippi.

The Code of Ethics of Oregon.—In a bill before the Oregon legislature, for the regulation of medical practice, there is a singular clause providing that licences to practise may be revoked for "unprofessional conduct," which is defined in the bill as: (1) Participation in criminal abortion; (2) employing "drummers or steerers;" (3) promising to cure an incurable disease, and taking a fee therefor; (4) betrayal of a professional confidence; (5) advertising in a false or exaggerated manner; (6) advertising to regulate the menses of women; (7) conviction under some charge implying "moral turpitude;" (8) habitual intemperance. Like many other newly settled communities, Oregon has greatly suffered from quacks and advertising adventurers.

There is a movement on foot at Paris to establish a polyclinic, conducted similarly to those of Vienna and Berlin.

Official List of Changes in the Stations and Duties of the Medical Corps of the U. S. Navy for the Two Weeks Ending July 12, 1890.

P. H. Rixey, *Surgeon.*—Leave of absence granted for fifteen days.

F. M. Ogden, *Assistant Surgeon.*—Promoted to be a Passed Assistant Surgeon.

S. Stuart White, *Assistant Surgeon.*—Promoted to be a Passed Assistant Surgeon.

L. W. Atlee, *Assistant Surgeon.*—Granted three months' leave of absence

T. Wolverton, *Medical Inspector.*—Awaiting orders to the U. S. S. "Philadelphia."

P. A. Lovering, *Passed Assistant Surgeon.*—Awaiting orders to the U. S. S. "Philadelphia"

D. McMurtrie, *Medical Inspector.*—Granted leave of absence for thirty days.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 8 to July 14, 1890.

By direction of the Secretary of War, the leave of absence on surgeon's certificate granted Marcus E. Taylor, *Captain and Assistant Surgeon*, in S. O. 45, June 13, 1890, Division of the Pacific, is extended five months on surgeon's certificate of disability, with permission to go beyond sea.—Par. 6, *S. O. 159, A. G. O.*, July 10, 1890.

ORIGINAL LECTURES.

AMPUTATION OF THE NECK OF THE CERVIX UTERI. DYSMENORRHŒA FROM CERVICAL STENOSIS.

A Clinical Lecture
delivered at the Hospital of the University of Pennsylvania.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

[Reported by LEWIS H. ADLER, Jr., M.D.,
RESIDENT PHYSICIAN EPISCOPAL HOSPITAL; LATE RESIDENT PHYSICIAN UNIVERSITY HOSPITAL.]

GENTLEMEN: My first case to-day is one upon which I operate under a sort of protest, because I am not certain that it will be followed by success. Yet, taking all the circumstances together, I feel that it is the safest and best thing that can be done.

The history of the patient is briefly as follows: The woman is thirty-three years old, married, but sterile and very anxious to become a mother. A few years ago she began to lose much blood at her menstrual periods. This menorrhagia has now become a serious matter. The cause of this excessive hæmorrhage is a multiple fibroid tumor of the womb: more than this, she labors under the physical defect of having the surgical neck of the womb elongated to the length of one and a half inches, and this mechanically interferes with coition to the extent of preventing any semen from entering the uterus. I operate to-day, first, on account of the tumor, and, in the second place, on account of the sterility. On account of this tumor the woman is losing each month a serious quantity of blood; now, if through an amputation of the cervix she be enabled to become pregnant, two very important objects are gained—in addition to the sterilty being cured, the pregnancy will stop her menstruation, and thus for the time prevent the loss of blood, and probably, also during her lactation. By the blood-currents being directed into other channels during these two periods—of pregnancy and of lactation—and by the positive influence that the act of involution will exert to divert the blood from the uterus, there will be a strong tendency and even a great probability that the fibroids in the walls of the womb will become actually smaller.

I have in two instances delivered women with uterine fibroids, in whom the tumors afterward became smaller, although for a time there was excessive hæmorrhage; because, in both cases the tumors, being intra-mural, acted as splints to the walls of the uterus, and prevented the womb from contracting. I know of another case in which a doctor delivered a woman who had a fibroid tumor weighing thirty pounds. In that case the labor came on and ended without difficulty, the hæmorrhage being very slight, because the tumor was subperitoneal. The final result was not so successful, as the woman died in two days from septicæmia, which disease was caused, as the post-mortem examination revealed, by broken-down uterine tissues, which in many places had become necrotic and had further degenerated into pus.

There are, in general, three ways in which fibroids of the uterus prevent conception:

The first of these ways is by menorrhagia. The excessive flow of blood washes away the ovum before it is impregnated, or, at any rate, prevents its becoming moored to the side of the womb, to undergo there its complete development. For this reason the fibroid that causes the greatest hæmorrhage will be the most apt to prevent conception. So that pregnancy is more common with subperitoneal fibroids than with the other two varieties.

The second way that a fibroid prevents conception is by causing the Fallopian tubes to become tortuous, which condition, by narrowing the calibre of their canals, delays or prevents the passage of the ovum to the uterus.

Lastly, in the vast majority of cases of fibroid tumors the ovaries and tubes are themselves the seat of disease; in some instances being affected with inflammatory changes; in others, with cystic degeneration.

Now, in the case before us, the woman is anxious to have a child, and I would feel warranted in removing the tumor, provided I was certain that she would then become pregnant; but really, with the elongated condition of her cervix uteri, I think that, if all other obstacles were removed, she would still be mechanically incapacitated from conceiving. For, as I press down the womb from above, and, at the same time, dilate the vaginal canal, you can see in this instance a redundancy in both lips of the cervix, which condition has been compared to a shark's mouth or to a tapir's nose, and as you know the latter resemblance has given rise to the expression of the "tapiroid cervix." The measurement of the normal uterus gives minus five inches, while from the beginning of the present cervix, I get a measurement of plus five inches. Therefore what I propose doing to-day is to amputate about one inch and a half of this redundant cervix with the hope that she will then become pregnant and that thereby the menorrhagia may be stopped and the fibroid tumor grow smaller.

In this case, the operation of amputating the cervix is complicated by the presence of the fibroid tumor, which has for a long time been inviting a large quantity of blood to the uterus, so that from this excessive nutrition of the endometrium there is upon it an outgrowth of vegetations. These will have to be scraped off, and in order to do this the cervical canal must be made large enough to allow the curette to pass through. Therefore, the operation to-day would naturally divide itself into three stages:

1. Dilating the cervical canal;
2. Scraping the cavity of the womb; and,
3. Amputating the redundant part of the cervix.

But, I find that in this instance I cannot follow these stages of the operation in the order given; because the cervix is so long that when I attempt to dilate it the shoulder of my dilator will not allow the instrument to pass far enough in, so that I find myself obliged to begin with the amputation.

The first step is to disinfect thoroughly the instruments. For this purpose I prefer to use a 1-to-2000 solution of the bichloride of mercury. I am fast giving up the use of carbolic acid as a disinfectant, not only on account of its odor, but also because it does not compare with the solution of the bichloride of mercury as a germicide. The drawbacks to the use of the latter are that it is a very poisonous drug to handle, and that it is injurious to instruments, especially dulling the edges of sharp tools.

The vagina may be thoroughly washed out with a 1-to-1000 or 1-to-1500 solution of the bichloride solution.

The patient, now being fully under the influence of the anæsthetic, is placed upon the table in the lithotomy position, on the left side, and a Sims's speculum is introduced and given to my assistant to hold. I now bring the womb fully into view and introduce into the bladder a well-curved sound in order to determine its situation in relation to the uterus; next, the cervix uteri is transfixed with a long, straight skewer just above the point at which I propose to amputate, and another one is placed at right angles to it. Behind these an elastic noose of rubber tubing is tied to control the hæmorrhage, after which the redundant portion of the cervix is removed in a cone-shaped piece.

One danger in this operation is the possibility of accidentally getting into Douglas's pouch. I am certain that during my professional career I have opened this pouch once and possibly oftener, but with very little bad effects.

The little hæmorrhage which you notice is no more than will be controlled by the stitches. When it is excessive Paquelin's cautery is the quickest and surest means of stopping it. Having now removed the redundant part of the cervix, which, as it is now bloodless, appears much smaller than it did a minute ago, I prepare to unite the mucosa of the os uteri with the mucosa of the vagina by means of silver-wire stitches, which, in their radiating arrangement, resemble that of the spokes of a wheel. I say, I prepare to unite, because I shall not complete that part of the operation, but when I have finished the remaining two stages of the operation Dr. William L. Taylor will kindly take her outside and unite the sutures.

I next proceed to dilate the cervix to one and one-sixteenth of an inch, which, in this woman, is rendered more difficult than usual on account of the long, narrow cervical canal. This being done, I now prepare to use the curette, which instrument I grasp gently, both that I may not inflict any injury on my patient and that I may the better appreciate the character of the surface over which it moves. Upon inserting the instrument I feel as I pass it around within the cavity of the uterus projections here and there, also a ridge of fibroid tissue over which the curette passes.

I should have told you that the instrument which I use for this purpose is always the sharp curette, which makes great care necessary.

Before beginning this curetting I had washed my instruments in a strong bichloride of mercury solution and also had the vagina syringed out with a 1-to-1000 solution of the same material. Now that it is over I wish to disinfect the parts once again with this 1-to-1000 solution. I therefore syringe out the vagina, and, as I want some of the solution to go into the cavity of the scraped womb, I gently swab out the endometrium. It would be highly dangerous to syringe the uterine cavity in this condition, because if the organ were to contract and the os not remain patulous so that the solution could readily pass out, the imprisoned liquid might be forced through the Fallopian tubes into the cavity of the peritoneum. Therefore, the rule is never to syringe into the uterine cavity unless you have a perfect avenue of escape.

[The patient was now removed.]

This condition of cervical elongation upon which I have just operated was a congenital defect. There is, however, a hypertrophic elongation of the cervix, following laceration, and due to the parts being rendered more plastic than normal by their increased blood supply. The operation on the laceration in these cases does not, in my experience, cure the elongation. There happens just now to be in my private hospital a case of this kind that has been operated on by another physician for laceration of the cervix and yet the organ protrudes from her person.

After these operations there will be around the os uteri a raw surface that will heal by granulation; this fact, together with the irritation set up by from fifteen to twenty sutures, may cause so great a degree of retrograde metamorphosis that a womb that gave a measurement of from four to five inches may be made to shrink to only two inches. The weight of the organ is correspondingly diminished, and as the uterus rises in the pelvis the cervix will then seem shorter than it really is. Paquelin's cautery may also cause cicatricial contraction.

There are two accidents to avoid in this operation. They are, getting into the bladder and as before stated getting into Douglas's pouch. The first of these is guarded against by passing a catheter into the bladder or by passing the finger through the dilated urethra, that it may serve as a guide. I have never yet met with this accident, though I fear I shall some day, for it has happened already to a good many of my brother practitioners. If such an accident were to happen to me, I would at once close the wound with sutures. The other accident, as I said before, has happened to me at least once, but without fatal result. In Die Allgemeine Krankenhaus of Vienna there are no special precautions taken by the operators to avoid opening Douglas's pouch, and they show most excellent results in their operations. The great secret is to have everything antiseptically clean, and then there is comparatively little danger even if we enter either place.

DYSMENORRHŒA FROM CERVICAL STENOSIS.

This woman is married and has had no children, although she has wished for them. She seems to be, physiologically, a perfect woman, and her husband also presents all the qualities of being a perfect physiological man. In the vast majority of virgins and barren wives you will find an anteflexion of the womb, and, while I have not yet examined this woman and so cannot be positive, I think it most probable that I shall find here a case of exaggerated anteflexion and that it is this condition that

makes the cervical canal narrower at the os uteri. I often compare this condition to a bent rubber hose, in which the angle causes a lessening in its calibre; and just as the normal calibre of the hose can be restored either by means of straightening or by dilating it at that point, so the diameter of the cervical canal may be made normal either by overcoming the anteflexion or by forcible dilatation.

The first of these objects is attained by means of the pessary. All kinds of these instruments, especially the intra-uterine stem pessary, have been used with more or less benefit. But they are all fast going out of fashion and are much less popular than they were ten years ago. As a rule, I do not advocate their use; but I do like and can most heartily recommend the use of forcible dilatation. By this latter means the result desired is attained without the discomfiture of carrying a pessary; the woman becomes pregnant, and the birth of the child straightens out any angles that may exist in the canal. I have performed this operation about three hundred and fifty times and have never had cause to regret it, and neither will you, provided you are careful to use the one great precaution which may be embraced under the expression "thorough antisepsis." The steps of this operation are as follows: First I introduce into the rectum a suppository of the aqueous extract of opium. This is done before I begin to dilate, so that its effects will be manifest by the time the operation is completed. Next, before introducing the speculum, I disinfect the vaginal canal by thoroughly swabbing it with a 1-to-1000 solution of the bichloride of mercury. I now put in the speculum, not greased, but rendered antiseptic with this same solution. This being done, I again disinfect the vagina and then feel that at least the avenues are antiseptically clean. The passage of the sound caused the discharge of about half a teaspoonful of mucus, which is always a good sign. I now introduce my smallest dilator; upon it I have no rachet, for I consider it both unnecessary and dangerous to the operator, as the rachet is liable to slip and cut the hands. After using this instrument until I have made the canal large enough for my larger dilator, I withdraw the smaller one and insert the larger size, with which I enlarge the canal to the extent of one and a quarter inches in diameter.

There is here a little bleeding, as is often the case, and it would be of no consequence except that it interferes with the means of antisepsis. However it quickly stops. If it were to bleed too much, I would use injections of alum or of vinegar; and then, if it were to continue, I would tampon the vagina with antiseptic lint. But in this case all such measures are unnecessary. I again syringe out the vagina with a strong solution of the bichloride of mercury and then, after drying it with an antiseptic swab, I introduce a ten-grain suppository of iodoform, and the operation is done.

When she comes from under the influence of the ether, she will have another opium suppository; two hours later, if she be suffering much, she will have a third, which will be repeated in a couple more hours, if it be necessary. This is generally all that is needed. To-morrow the nurse will syringe out the vagina, both morning and evening, with a 1-to-4000 bichloride of mercury solution, and will repeat this as often as necessary. I formerly used a 1-to-2000 solution, but I collected thirty or forty cases in which I think that it proved injurious, so that I have ceased to use it so strong. This patient will stay in bed until all soreness is over, and I shall continue to use every antiseptic precaution until all danger is past.

ORIGINAL ARTICLES.

WHAT CAN AND SHOULD BE DONE TO LIMIT THE PREVALENCE OF TUBERCULOSIS IN MAN?[1]

BY EDWARD O. SHAKESPEARE, A. M., M.D., PH. D.,
OF PHILADELPHIA.

UNDOUBTEDLY the great majority of advanced thinkers of our profession in Europe and America, to-day admit that Villemin (whatever may have been the reception first accorded his publications) announced a most important truth in 1865 when he declared, from the standpoint of experimentation, that tuberculosis is a specific infectious disease; and unquestionably the same men now acknowledge that Koch in 1882 not only signally confirmed this truth of Villemin, but greatly increased its practical importance by proving that the tubercle bacillus constitutes the sole specific infection of this disease.

It is not my purpose, and, in my opinion, it would waste valuable time to review even cursorily the evidence which now unshakably supports the claims of these two distinguished investigators. Nor can I hope to present anything new.

I think I may safely advance the assertion that there is no fact within the whole range of medical knowledge for the demonstration of which a greater mass of the most exact, positive, convincing proof can be marshalled, than that the bacillus tuberculosis is the sole active exciting cause of tuberculosis, and that without the agency of this micro-vegetable parasite there can be no genuine tuberculosis, no matter how susceptible the individual or how favorable the so-called predisposing causes may be.

Is tuberculosis essentially *infectious* and at the same time essentially *hereditary*? Although we have some examples of infectious diseases which are also at times hereditary, and at least one striking instance where a highly infectious disease—namely, syphilis—which is perhaps as frequently transmitted directly to the offspring *in utero* as it is acquired after birth by direct infection, there is strong reason for holding that, as a rule, diseases which are essentially infectious are also essentially non-hereditary.

What relation has this rule to tuberculosis? Of the analysis of clinical experience upon this question the best that can be said in favor of heredity is that the latter utterly fails to account for the origin of

[1] Read before the Association of American Physicians, May, 1890.

from 66 to 80 per cent. of the cases of this disease. On the other hand, autopsy records show that tuberculosis *in utero* is the rarest of all affections, in spite of the fact that death from tuberculosis is far more frequent in man after birth than is death from any other disease. In truth, all the fairly authentic observations of tuberculosis in the human newborn can be counted on the fingers of one hand, and I am cognizant of but two of these where the lesions have been shown to be genuine, and not pseudo-tubercles, by the presence of the bacillus tuberculosis or by the test of inoculation. In the bovine species, notwithstanding the great prevalence of tuberculosis among them, such observations are also exceedingly rare.

It seems therefore that we have ample ground for the belief that while tuberculosis is essentially infectious it is *essentially non-hereditary;* at least the burden of proof now rests upon those who hold the contrary opinion; and the character of the proof they would offer must be unimpeachable and convincing, affording no opportunity for dubious conclusions. Until such proof to the contrary shall be forthcoming, there seems to be sufficient warrant for regarding the non-hereditary nature of tuberculosis in man as not only highly probable but as well enough established to constitute a very important factor in determining upon a series of judicious, practical, and comprehensive measures of prevention.

To express thus positively acceptance of the conclusion that tuberculosis in man is essentially infectious and essentially non-hereditary, is by no means to affirm that the influence of heredity has nothing to do in any case with the existence of this disease. That the tubercle bacillus is the sole active infectious agent in the causation of tuberculosis is no more certain than that the influence of predisposition or susceptibility of the invaded organism greatly favors the pathogenic action of that parasite after it has found a lodgement in the tissues of the body, and that it oftentimes alone makes the development of the implanted seed possible, where otherwise a comparatively barren soil or other unfavorable conditions might prevent fructification. Marked predisposition or susceptibility to the development of tuberculosis upon *post-natal* infection may undoubtedly be an inheritance transmitted from a tuberculous parent to a child—a transmitted vulnerability which, let us hope, may be within the power of the family physician, through wise counsels respecting hygienic surroundings, wholesome nutritious food, and judicious physical culture, to do much ultimately to remove.

In recent discussions concerning tuberculosis and the practical value of the lately acquired knowledge of the pathogenic and biological characters of the bacillus tuberculosis, we hear much, especially from those chiefly interested in clinical medicine, of the complaint that this great discovery has not yet contributed, and probably never will contribute, anything toward the cure of the disease.

What if the great Koch and his co-laborers in that new field of etiological research have utterly failed to strengthen our hands by placing therein an efficient means of curing tuberculosis! Cannot a very similar reproach be applied with equal justice to Pasteur and his discoveries concerning the cause of morbid fermentations in beer and wine; concerning the cause of *cholera des poules*, of charbon, of *rouget du porc*, and of rabies? Yet what reasonable man would question the fundamental importance and immense practical value for prophylaxis of Pasteur's discoveries because he has not also shown how beer and wine once ruined by the products of morbid fermentation can be restored; or how a chicken seized with cholera, a sheep attacked with anthrax, a hog suffering with rouget, a human being already in the frightful convulsions of hydrophobia, can be cured? Who would demand of him who should come to us with a new and far more effective means than we now possess of arresting or markedly impeding the spread of an epidemic of scarlet fever, diphtheria, yellow fever, or cholera, that he shall first add something to the treatment of these diseases before his proposed measures of prophylaxis, which might be freely acknowledged to be broadly based upon entirely adequate experimental tests and supported by the strongest theoretical deductions, shall have a practical and thorough trial?

In dismissing this point, permit me to suggest that untenable as such a position would be, it is nevertheless very similar ground upon which those stand, in this country and elsewhere, to-day who, acknowledging the infectious nature of tuberculosis and the tubercle bacillus as the sole active cause of the disease, attempt to excuse or justify inaction upon the valuable knowledge we already possess concerning etiology and prophylaxis by lamenting that Koch and all other bacteriologists have failed to suggest, with their prophylactic measures, an effective mode of treatment.

In view of the admitted inefficiency of all present modes of treatment of actual cases of tuberculosis, I hold that effective prophylactic measures are infinitely more important to the general public, and should also be to the physician, than the most skilful therapeutic treatment of the disease can possibly be at the present time.

If ever there were reason for quoting the time-worn saying, "an ounce of prevention is worth a pound of cure," there certainly is when discussing the relative importance of treatment and prophylaxis of tuberculosis—a malady which more than decimates the human race, and against the ravages of

which even the most skilful physician has ever been powerless.

"What can and should be done to limit the prevalence of tuberculosis in man?" This, in my opinion, is one of the most important questions with which we as physicians can deal. It is for this reason and also because it seems to interest the clinician but little at present, in comparison with the therapeutics of the disease, that I selected this subject for presentation before a society formed mainly of clinicians, with the hope of provoking a discussion and thereby hastening the time when the clinician shall earnestly unite with the hygienist in an active incessant warfare for the extermination of that terrible scourge of man, the deadly tubercle bacillus.

While, on the one hand, the discovery of the bacillus tuberculosis has, as far as we now can see, little advanced the clinical management and cure of tuberculosis except by furnishing a reliable and ready means of early diagnosis; on the other hand, it has revealed most important principles upon which to base efficient means of preventing, or, at least greatly limiting the extension of the disease—an end which may be rightly regarded as of far greater moment.

Ernst rightly declares that "Proper methods of management of tuberculosis, both in human beings and animals, involve more important interests—pecuniary as well as vital—than any other subject that engages the attention of medical men."

What are the general principles which underlie a comprehensive and effective system of prophylaxis of tuberculosis?

I hold them to be essentially these:

1. Destruction of the vitality of the tubercle bacillus wherever it may be found outside of the human body.

2. Avoidance by the unaffected of unnecessary risk of introduction within the organism of the living bacillus tuberculosis.

3. Improvement of the vitality of the individual, his personal hygiene and that of his dwelling in order that conditions unfavorable to the presence, vitality, and development of the tubercle bacillus shall prevail as widely as possible.

I have named these three fundamental principles in what appears to me their order of relative importance, well aware that many distinguished clinicians look upon the last named as that which alone should receive their hearty sanction and support. I have rated the last as least important for three reasons, each of which I regard as sufficient:

(*a*) Because analysis of the fullest records we have, bearing upon the relation of family history to the causation of tuberculosis, can possibly account, through the influence of hereditary predisposition or vulnerability, for little more than one-fourth of the actual cases of tuberculosis.

(*b*) Because, in the first place, the percentage of the so-called predisposed who could be induced to coöperate intelligently with the physician would be small; and, in the second place, it is highly probable that by no means all of even that small percentage could be so built up permanently that every vestige of inherited vulnerability would be removed.

(*c*) Because, even when this inherited susceptibility may be successfully removed by such efforts, we have to deal with an infectious poison which, if not destroyed, is virulent enough to produce the disease not alone in the comparatively few who may be born with an hereditary predisposition, but even to cause tuberculosis in the great majority who succumb notwithstanding the absence of an hereditary weakness.

I have not thus estimated the value of this means of combating the prevalence of tuberculosis for the purpose of indicating that it should be wholly discarded. On the contrary, I hold that it is incumbent upon us to wage an incessant and relentless warfare against the cause of this disease, "with all the means which God and nature have placed in our hands." But, let us not indulge the delusive hope that only by the selection and even skilful use of the weakest and shortest-ranged weapons we can "successfully cope with so formidable an adversary;" and let us not imagine that when we have done so we have performed our whole duty as physicians.

It is the seed of the disease, without the implantation of which there can be no harvest of death, that we are now most able to reach and destroy, and I hold that, both as clinician and hygienist—interested as well in the prevention as in the cure of disease—the true physician should do his utmost to eradicate the seeds of this malady.

It is, therefore in my estimation, the first two general principles which should form a basis for development of details of the means which can and should be adopted at the present time for the limitation of tuberculosis.

But it has not been my purpose here to suggest in detail the prophylactic measures which should be widely adopted and enforced against the spread of tuberculosis. Excellent regulations—the general observance of which would certainly accomplish much toward the ultimate extermination of this disease, at least in its present pandemic form—have been presented by numerous physicians and health authorities.

My sole object has been to lay this important matter before the Association of American Physicians in such a manner as to elicit some action, or, at least, expression of opinion, relative to the urgent necessity of doing something—as a representative

body of leaders and advanced thinkers in our profession—which shall aim at the limitation of this disease by effective prophylaxis.

Do we admit that tuberculosis is an infectious disease? Then let us so declare. Do we believe that this disease rarely, if ever, has a truly hereditary origin? Then let us not hesitate to publish that belief. Do we acknowledge that the tuberculous, especially in the active stages of the affection, throw off in the sputa or in other discharges the infectious principle of the disease, and thereby jeopardize, whether little or much, the safety of the healthy? Then let us boldly publish our knowledge, for the benefit of the public who are not in possession of it. Are we convinced that the meat and milk of tuberculous animals often contain the infectious poison and produce the disease in the healthy consumer? Then let us, without further delay, strenuously and unitedly demand the vigorous inspection of the meat and milk supply and the prompt destruction of the affected animals. Do we agree that habitations become infected with virulent sputum from the consumptive and constitute a danger to the other inmates? Then let us insist upon thorough disinfection and immediate destruction of that dangerous matter. Is it probable that an injured condition of the lungs or of other exposed organs increases the risk of development of tuberculosis after exposure to the infection? Then let us prevent many a case of consumption by insisting upon the removal of phthisical patients from the general medical wards of hospitals. Are we convinced that the unfortunate subject of tuberculosis constitutes a migrating centre of possible infection? Then let us warmly advocate the establishment of special consumption hospitals.

Now, brother clinicians, I hold that all these things can and should be done to limit the prevalence of tuberculosis in man. But they can be done only through your influence in forming public sentiment by spreading broadcast the knowledge which we possess concerning these vital matters, and thus limiting to no inconsiderable extent public dissemination of tubercle bacilli.

AMPUTATIONS WITH REFERENCE TO THE ADAPTATION OF ARTIFICIAL LIMBS.[1]

By A. H. GARNETT, M.D.,
of Colorado Springs.

I am not of those who believe that, "An amputation is an opprobrium to the art of curative surgery," nor am I ready to subscribe wholly to the faith, "that in the present rapid advance in the science, and the greater perfection in the art, the time is not far removed, when amputations for cause other than gangrene, will be rare." That in the thorough observance of the practice of asepsis, founded upon the bacterial origin of disease, the saving of life and limb under conditions seemingly hopeless, is now made possible, I am free to admit; but so long as there are incurable diseases, so long as there are unavoidable accidents, just so long will the necessity for amputation exist. Mechanical skill and ingenuity find a rich and varied field in the domain of surgery, for the exercise of inventive genius, and with a perseverance worthy of so good a cause, the laborer here, by the application of principles based upon the study of physiological anatomy and mechanical philosophy, has in this country brought the art of prothesis to a degree of perfection that has exerted and must continue to exert a potent influence upon amputations with reference to the successful adaptation of artificial limbs.

Statistics compiled from authentic sources show that nearly 33⅓ per cent. of the limbs lost are traceable directly to railroad accidents. Add this fact to the philanthropic spirit which prompts in many instances the generous hand of corporations to furnish appliances to the unfortunates thus crippled in their employ, and to those of us engaged in the medical service of a railroad, and we have a subject at once of personal interest.

Singularly enough, and unfortunately, the text-books, including Ashhurst's *Encyclopædia*, are content to pass this subject by with scarcely a reference, with the single exception, so far as I have been able to find, of Dr. S. D. Gross, who with a just appreciation of its growing importance, and with that intuitive grasp of the practical in his chosen profession, for which he was so notably and eminently endowed, after paying a graceful tribute to the manufacturer's worth, aptly says:

> "Great improvements have of late years been effected in the construction and adaptation of artificial limbs, and there is reason to believe that the inconvenience and suffering occasioned by their use are more frequently attributable to the misconduct of the surgeon than to the want of skill on the part of the manufacturer of the substitute."

Here then we have the key-note as it were from the "Nestor of American Surgery" upon the subject under consideration, who in a single terse sentence makes the relation of operator and manufacturer one of mutual dependence and profitable study.

In the absence of any literature upon the subject at my command, and without that individual experience which carries with it the force of authority, I have been obliged to consult by letter some of the leading makers of artificial limbs, whose daily observations in the construction and adjustment of these substitutes and of every variety of method practised by various operators entitle their opinions and suggestions to a respectful hearing, and to them for their kind responses I owe my thanks.

[1] Read before the National Association of Railway Surgeons, May, 1890.

There is a unanimity of opinion among the makers that the surgeon should have some knowledge of the mechanism, construction, points of bearing, etc., of artificial limbs. I opine that from this position none of us are prepared to dissent, since the ignorance of the average medical man in this particular direction is admitted, at least among ourselves.

A few hours devoted to the perusal of the descriptive pamphlets issued by the more prominent and larger dealers will be all that is needful to acquire this knowledge.

In considering the subject proper, let us begin with amputations between the articulations, or, more definitely speaking, through the shafts of the long bones. The method generally adopted is either that of anterior and posterior, or of lateral flaps, and, as usually performed, the flaps are of the same length, or very nearly so. The stump at the extremity is frequently in consequence but poorly protected, the tissues are more or less adherent, the bone is protruding, and the cicatrix is immediately over the projecting surface; the weight is necessarily taken upon the sides, and upon the enlarging part of the stump. In the thigh, for example, the weight is taken above the end and about the ischium. This necessitates to some extent traction upon the cicatricial tissues covering the end, and this tissue from its non-elasticity and hardness exerts a certain amount of pressure upon unyielding parts; nerve filaments are caught and compressed in the opposing surfaces and as results we have painful sensations and disturbances of nutrition and circulation. To obviate this in a measure we are asked to carry the flap well to the posterior, having taken the precaution to protect the bone with periosteal covering. The cicatrix, by observing this rule, will be distant from the end of the bone, and removed from pressure. A good cushion without cicatricial tissue will form the covering of the extremity, and although it is not intended that the apparatus shall press principally on this point, if it should do so to a slight degree no harm will result. The nerve conditions resulting from adhesions, cicatricial pressure, etc., will be in a measure avoided and the liability to these altogether too frequent complications will be greatly lessened.

The above rule applies with equal force to amputation between the knee and the ankle. Teale's method here as in the thigh seems to fulfil the indications admirably and is well and favorably spoken of. When a choice is possible between the knee-joint and a position immediately above or below, preference is given to disarticulation.

The practice with some operators of trimming the condyles, is condemned upon the grounds of removing the natural cushions, rendering the end incapable of bearing weight, which, contrary to the teachings of some authors, is taken preferably at the extremity, particularly if the patella can be made to fit into the condyloid space without the probability of becoming displaced. The flap here too should be long and anterior so that the cicatrix will not be pressed upon. When the operator is compelled to go below the knee the juncture of the middle with the lower third should, if possible, be selected, since we are told that no advantage can accrue from leaving bone between this and the ankle, a mistake not infrequently made by the surgeon. The want of space preclude the possibility of constructing a suitable artificial limb.

Amputations through or below the ankle-articulation are performed in the main with the view of receiving the weight upon the plantar surfaces; this result is generally obtainable, and a limb capable of doing good service is left. But the question presents itself, whether the amputation should be made with reference to leaving this natural support or for the better adaptation of an artificial appliance. The financial and social standing of the patient will enter largely into the decision. If the conclusion to act with reference to the adaptation of an artificial limb is reached, then the surgeon must be governed by the suggestions of the manufacturers; since they tell us that amputation in this locality involves one of the most perplexing problems in prothetical science.

I cannot do better in this connection than to use the words of Mr. A. A. Marks, of New York, whose excellent pamphlet should be in the hands of every surgeon. Mr. Marks tells us that the amputations through the metatarsus, known as Hey's and Chopart's, leave the most troublesome stumps, and mainly for the following reasons, which to my mind appear good and sufficient: 1. The natural length of the leg from the knee to the heel is retained, thus allowing no space for attachments or mechanism in the appliance. 2. All dimensions of the stump from the end to the articulation are either normal or increased, and, as the appliance must encase the stump, the diameters about and below the ankle are necessarily very much larger than natural; this gives the apparatus an unsightly and clumsy appearance. 3. The stump will not permit a firm grasp, as the remaining bones and the nervous mechanism of the foot are such as to forbid continuous pressure. On account of this the ankle-joint articulation cannot be used; for, in order to secure an artificial foot to the stump, the pressure must be considerable. Among the most serious objections, however, that Mr. Marks urges, and which alone in his estimation should condemn the operations, is the disposition of the amputated surface to point downward, occasioned by the severance of the flexors, thus destroying all opposition to the extensors. The division of the tendo-Achillis to obviate

this difficulty, he tells us, affords only a partial relief. The operations at the tibio-tarsal articulation, known by the names of Syme and Pirogoff, have so many advantages over all others, fulfilling, as claimed, the most important conditions and at the least cost to the wearer, that they should always, if possible, be chosen. It is well perhaps, in connection with this, for us to recall the fact that the Syme operation has grown somewhat into disrepute among some surgeons because the necessity for reamputation is greater by about three per cent. in this than in any other amputation. The cause recently assigned for this by some authors is the failure to appreciate the importance of making the plantar incision far enough forward, as recommended and emphasized by Syme himself, and of preserving the proper vascular supply to the posterior flap.

In amputations of the upper extremities one broad guiding principle should govern us, namely, extreme conservatism; save everything possible, for the best devised substitute known to the art is here far inferior to nature's provisions and but a poor aid at best.

To recapitulate briefly, the most desirable points for amputation in the thigh and leg are the lower thirds. When the operation must be in close proximity to the knee, the articulation should be selected as more available than a position immediately above or below.

In amputations near the ankle the tibio-tarsal, Syme's, or Pirogoff's method should be chosen. It is evident that the point of selection is not always within the power of the surgeon to decide, owing to the nature of the injured part. We are assuming that it is practicable; that it is opposed to the former practice of saving in every instance "as much of the maimed limb as is consistent with the life of the patient," and that the decision conforms to the proper adaptation of the more perfect compensative appliances of the present.

The after-treatment of the stump comes in here for our attention. One of the principal objects to be attained in an amputation is a good stump. This ideal may appear to have been obtained when the wound heals, but with the lapse of time we may note changes in its integrity, the muscles, soft parts and bone to some extent atrophy, the latter may become necrosed and the extremity painful. Some recent researches by a Frenchman, whose name I do not recall, have thrown light upon this important point. He states that a stump is a distinct organ; that it has its own life, its special innervation and vascularization. His studies have been mainly with the venous supply heretofore neglected, and he traces the anatomical relation of this system throughout its most minute ramifications and connections, showing wherein the superficial supply is feeble and deficient. An important element in the production of the venous circulation he finds wanting, namely, muscular compression, as the muscles about the cicatricial plexus are represented mostly by fibrous lamellæ. This condition explains how external agencies, such as cold, etc., bring about reaction in the end of the stump, forcing the blood from the superficial network into the deeper veins causing neuromata, congestion, pressure, and pain. It is within the power of the surgeon to crowd out the fatty tissues and to solidify and harden the stump, making it richer in blood-supply, by a systematic process of bandaging tightly, bathing, rubbing, etc.; increasing and exciting the circulation and enlarging bloodvessels. It is highly important that this condition of the stump should be attained before our patient comes to the hands of the manufacturer for the fitting of an artificial limb. It is true that these changes will be brought about by the pressure of the apparatus, but with the shrinking of the stump the appliance becomes loosened, necessitating a second fitting.

The final question for us to consider and one with which we will be frequently confronted, is, How long after an amputation before an artificial limb can be properly applied? Of course there are many determining conditions and circumstances, but as a rule the experience of both surgeon and manufacturer agree, that the apparatus should be applied as soon after perfect healing as possible. Among the theoretical and physiological reasons deduced to support this position by those in military practice and by government inspectors of artificial limbs, may be mentioned the well-known law that the muscles after an amputation become weak and undisciplined from the loss of that nice balance and coöperation that is natural between them and the will-power, and that in consequence the ability to control the movements of the stump and of the apparatus will be to a great degree lost.

The application of the substitute is the first stimulus that serves to arouse the muscles from a state of comparative inertia or inactivity. Increased tone and strength are imparted, the tendency to waste or atrophy is prevented and the disposition to the accumulation of adipose tissue is materially checked.

Is will be observed that I have purposely avoided entering at length into the many methods of amputating, which would be a wearisome repetition of unnecessary details with which all are perfectly familiar. I have merely attempted to give a brief outline.

Hospital Ships.—There are three floating hospitals in the North seas, designed to go from point to point among the deep-sea fishermen. The skippers of these vessels have been instructed to some extent in the principles of "first aid" in the accidents and ailments to which the fishermen are exposed.

MENTHOL IN DISEASES OF THE AIR-PASSAGES.[1]

BY SETH S. BISHOP, M.D.,
SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY, ETC., CHICAGO.

MENTHOL, a peppermint-camphor, is a powerful antiseptic and a local anodyne. I have used it considerably in a variety of diseases, and believe that its remedial properties entitle it to an important place in the work of general practitioners and of specialists. To speak systematically concerning the effects of menthol on the upper respiratory tract I will begin with the nose. Acute coryza or influenza in the first stage can be checked by inhalations or sprays of the drug. If the attack is a light one nothing is necessary beyond smelling the crystals contained in a wide-mouth vial or tube. I have aborted colds in the head at their onset by such inhalations of thirty minutes' duration. This, of course, was before the nasal irritation had passed to the stage of inflammation. The sense of fulness and constriction about the nose and frontal sinuses and the flow of mucus disappeared, the nostrils opened for the free passage of air, and complete relief followed. The remedy is well adapted for inhalation on account of its being very volatile. In the later stages of a coryza, where an actual inflammation exists before treatment, it is necessary to use sprays of menthol dissolved in liquid albolene, in order to protect the membrane and to keep the medicine in contact with the diseased surface a long time.

The strongest solution I have used was one of twenty per cent., but that is too powerful for most individuals. Five- or ten-per-cent. solutions are as strong as most people will bear. The sense of heat is considerable at first, and it materially contributes to the comfort of patients to instruct them to take several prolonged inhalations of air directly after using the sprays. This converts the burning sensation into one of agreeable coolness. Even in chronic cases of nasal catarrh I have been able to open a closed nasal passage by one or two treatments with a fifteen-per-cent. solution, thus affording great relief to mouth-breathers. Whenever a patient comes with turbinate bodies so enlarged as to obstruct the passage of air, and to prevent the entrance of sprays through the nostril to the throat, I resort at once to this remedy, with the effect of shrinking the engorged tissue and restoring the natural air-channel.

It is advantageous to prescribe inhalations of menthol for patients who take cold easily, so that they can employ the treatment at home whenever a coryza is coming on. A drachm or two of the crystals in a wide-mouth vial, with a metallic screw-cap, or a glass tube, is a convenient device. A pledget of cotton should be pressed into the vial to prevent the menthol from escaping and coming in contact with the nose, for it occasions smarting sensations wherever it touches the nostrils. If a large glass tube is used, both ends should be plugged with cotton-wool. As menthol does not melt at a temperature below 98° F., it can be carried in the pocket for ready and frequent use. When not in use, however, in should be tightly corked to prevent evaporation. In prescribing it for patients to use in atomizers it is best to use a solution not stronger than five or ten per cent., in oil. Albolene is preferable to fluid vaseline, for the latter alone often proves irritating to the mucous membrane.

In chronic hypertrophic rhinitis, with a foul-smelling discharge, menthol is sufficiently antiseptic and alterative to lessen the amount of discharge and to banish the odor. The peppermint aroma is usually agreeable, and more especially so when it supplants the stench of decomposition. In atrophic catarrh the stimulating properties of the drug, combined with the emollient and protective qualities of albolene, afford a means of speedy improvement.

Pruritus nasi yields to nothing, excepting cocaine, more readily than to menthol, and in connection with this, if it will not be too severe a tax upon our sense of continuity to pass from the upper air-passages to the seat of pruritus ani, I will remark, parenthetically, that menthol is vastly superior to cocaine in its effects here. I have seen the most exquisitely torturing itching and burning of the anus relieved in a few minutes by a twenty-per-cent. solution of this simple drug, after other ordinary and extraordinary remedies had utterly failed.

In laryngitis not dependent on a rheumatic condition menthol proves valuable. Even in rheumatic laryngitis it is an efficient adjunct to salicylate of sodium, iodide of potassium, etc. In simple acute laryngitis, if used in the early stage, it will relieve as it does in coryza, but the spray is the most effectual form in which to use it. When the soreness of the larynx and trachea, and hoarseness appear, a few inhalations of the spray often nip the attack in the bud. It relieves the hoarseness, and imparts a smooth, reed-like *timbre* to the voice. In advanced cases several inhalations of the spray should be used in the course of a day, and a continuous effect is often advantageous. This can be secured by keeping a saucer heated in the patient's room, and occasionally dropping a few of the crystals on it during the day and night. They melt readily at a low temperature, and fill the atmosphere with their penetrating fumes.

In whooping-cough I have directed patients to inhale constantly from a cloth saturated with a solution of menthol, and placed beneath the chin. Besides this I have sprayed the nose and throat daily, taking care to project the spray into the throat just at the beginning of inhalation. The

[1] Read before the Illinois State Medical Society, May, 1890.

paroxysms of cough were lessened in intensity and frequency, and the course of the disease appeared to be shortened. Bronchitis does better with this treatment than with other topical applications, or with internal medication alone. The spray should be inhaled after a forced expiration, and retained as long as possible in the bronchial tubes before the next inhalation. This brings the fine smoke-like vapor in contact with the diseased surface. It is best to have patients exhale it through the nose, and it can readily be seen pouring out of the nostrils for several seconds, after a forced retention, showing that the respiratory tract is thoroughly medicated. The effect is distinctly felt deep in the chest.

In catarrhal conditions of the Eustachian tube and middle ear I have employed menthol on account of its effect in relieving turgescence and stenosis in the nasal passages. I use the menthol in Buttle's inhaler as iodine crystals are ordinarily used, substituting cotton for sponges. If a stronger impression is desired I use the liquid albolene solution. Simply throwing the spray against the Eustachian orifices with the de Vilbiss' atomizer produces a thorough impression on the tube and tympanum.

Suppurative inflammation of the middle ear readily yields to the menthol treatment. Long-standing cases rapidly healed after the use of a twenty-per-cent. solution. I have just seen several cases of this kind in which the purulent discharge ceased after a few such applications. Furunculosis of the ear has been in my hands more amenable to this than to any other remedy. A pledget of cotton, moistened with a twenty-per-cent. solution, should be so placed that it will remain in contact with the centre of the furuncle. A warm or burning sensation follows, but soon gives place to one of coolness. The pain is relieved, the bacteria destroyed, and the swelling and discharge checked.

I have not yet used menthol in hay-fever, but have taken steps to give it a thorough trial during the summer by the members of the United States Hay-fever Association.

In corroboration of my account of the behavior of menthol in my practice I will briefly quote from a few authors on the subject. Mr. Lennox Browne says:

"Menthol contracts the capillary bloodvessels of the nose and throat, arrests sneezing and nasal discharge, stops pain and fulness of the head, and kills the microbe of infection. When the nasal discharge is excessive it is checked; when deficient and thickened, as in hypertrophic rhinitis, its healthy character is restored; and when it is arrested, inspissated, and malodorous, as in atrophic rhinitis, fluidity is promoted and the foul smell corrected."

William Hill, of London, claims to have found menthol an excellent substitute for cocaine in hay fever. Jones is authority for the statement that inhalations of menthol have proved useful in asthma. He used a twenty-per-cent. solution in olive oil, and relieved a case that had resisted all the common remedies. Nye says that these inhalations facilitate and diminish the expectoration in chronic bronchitis and relieve the cough. Potter and Knight have reported cases of improvement in laryngeal phthisis, and Rosenberg and others claim a large percentage of cures in this disease from the local application of menthol.

It is not my purpose to speak of the effects of this drug when administered internally, or when applied to the cutaneous surfaces for neuralgia, etc., but excluding these uses which are yet in the experimental stage, we are justified in according to menthol an important place in therapeutics.

70 State Street.

FIVE SURGICAL CASES OF SOMEWHAT EXCEPTIONAL INTEREST.

By CHARLES A. POWERS, M.D.,

SURGEON TO OUT-PATIENTS, NEW YORK HOSPITAL; ASSISTANT SURGEON TO THE NEW YORK CANCER HOSPITAL.

Case I. *Compound, comminuted fracture of the os calcis; partial resection, followed by primary union in the bone; large attached skin-grafts used; complete cure.*—A man, aged twenty years, was taken to the Chambers Street Hospital, October 11, 1887, with a history of having had the right foot caught between an elevator and its shaft a short time previous to his admission. In the absence of the attending surgeon, Dr. W. T. Bull, he fell under my care. He was found to have a compound fracture of the os calcis, it being broken transversely at about the juncture of its posterior third with its anterior two-thirds. The bone in the vicinity of this transverse lesion was severely comminuted, but there was no longitudinal fracture running through either its anterior or posterior surface. The posterior fragment hung dangling from the tendo-Achillis, which latter structure was intact. The interosseous calcaneo-astragaloid ligament was not broken. The soft parts were severely lacerated over an area which extended from the medio-tarsal articulation on the plantar surface of the foot to a point five inches above the insertion of the tendo-Achillis, and this area embraced the malleoli laterally.

The numerous small fragments of the os calcis were removed and the large fragments sawn transversely (Fig. 1), when by flexion of the leg and extension of the foot they could be approximated. A transverse hole was bored in each fragment and they were held together by heavy copper wire.

The lacerated and contused soft parts were freely cut away and the stripped-up plantar tissues were thoroughly drained. A large antiseptic dressing was applied and left in place for six days, when it was removed and reapplied. On the twentieth day there had been no pus formation. There was primary union in the bone, but there was a large open space at the heel about three inches wide by

seven inches long. This was dressed with balsam of Peru, and by repeatedly applied small skin-grafts it was reduced to an area of two by three inches. This was over the posterior surface of the os calcis, a surface which was the seat of necrosis below the insertion of the tendo-Achillis. The

FIG. 1.

Postero-external aspect of an os calcis (right). Approximately, the amount of bone embraced between the black lines was removed in Case I.

wires were removed on the forty-fifth day. A tendency to talipes equinus was overcome by an elastic band which was stretched between the upper part of the leg and the front of the foot.

The necrosed tissue on the posterior surface of the bone came away in due time, but despite the frequent application of small grafts an ulcer persisted over an area a little larger than a silver dollar.

The cure of this was undertaken, at my request, by Dr. Robert Abbe, who, in October, 1888, applied a large attached graft, which was dissected from the posterior surface of the calf of the opposite leg and sewn to the freshened ulcer. Primary union followed the procedure.

FIG. 2.

Result in Case I.

The young man now has a perfectly useful foot, the functions at the ankle being complete. Its antero-posterior length is seven-eighths of an inch shorter than that of its fellow.

The shortening in the os calcis has relaxed the plantar ligaments and fasciæ, letting down the head of the astragalus, and a moderate degree of flat foot remains, but this is corrected by an appropriately constructed shoe. (Fig. 2 shows the foot as it appeared one month after the application of the last graft.)

CASE II. *Dislocation of the right humerus of long standing, accompanied by exceptional displacement.*—A man, twenty years of age, presented himself at the out-patient department of the New York Hospital, December 1, 1889, seeking relief for the disability attending a dislocation of the shoulder of three years' standing. He gave the following history: In October, 1886, while at work upon a brush-making machine, his arm and forearm were caught in such a way that he was thrown forcibly against the machinery, the forearm being violently wrenched and the shoulder receiving a severe contusion. This accident was followed by pain and disability at the shoulder-joint, and in the following January he was admitted to a hospital where efforts were made, under ether, to afford him relief. He says: "The doctors said that my shoulder was dislocated, but that they could not keep it reduced—they could not prevent it from slipping out of place." He resumed his work as a brush-maker and was able to perform his duties with fair success.

When seen by me the humerus was the seat of an anterior dislocation, the head of the bone resting above and in front of the glenoid cavity. The deltoid was extremely atrophied. On passive motion the humerus could be made to undergo complete internal rotation, external rotation being a little restricted. Abduction was possible to but forty-five degrees.

When the arm was lifted the head of the humerus could be made to undergo a very marked excursion forward and upward, resting without and above the coracoid process (Figs. 3 and 4), and could even be forced to lie entirely above the clavicle.

FIG. 3.

Dislocation of humerus, Case II.

On bringing the elbow to the side, twenty degrees in front of the mid-axillary line, the head of the humerus could be forced into the glenoid cavity, or rather to a glenoid position, but when the force was released it would at once fly forward. When the elbow was at the side, and the head dislocated forward, the

right hand could easily be placed on the opposite shoulder. The axillary acromial measurement was three-quarters of an inch greater than that on the opposite side. The circumference at the middle of the arm and at the middle of the forearm was the same on both sides. The functions of the hand and forearm were excellent.

Fig. 4.

External aspect of shoulder, Case II.

The entire head, tuberosities, and neck of the bone could be intelligently palpated. At the inner side of the neck a prominent ridge could be distinctly felt, and the presence of this raised the question of longitudinal fracture at the time of the original injury.

Operative procedure for the relief of the disability was deemed inadvisable.

It would seem highly probable that the patient suffered, at the time of his accident, an anterior luxation, probably complicated by a longitudinal fracture through the upper part of the bone, and that constant use of the arm enabled the head of the humerus to make its wide excursion inward and upward. He states that in his work as a brush-maker he was obliged to draw the arm forcibly backward. In this motion the humerus would become a lever of the first class, the humeral head being the weight.

Case III. *Specimen of a simple fracture through the carpal scaphoid.*—This specimen was brought to me by Mr. L. T. Mason, one of my pupils in medicine, who had discovered an anomaly in the bones of a cadaver, during his anatomical studies. It was taken from a man of about fifty years, of whose previous history nothing, of course, could be learned. The bones of the upper extremity are all of exceptionally large size, and very well marked. All are normal except the scaphoid. This is the seat of a fracture which runs from before backward, dividing the bone into two portions, of which the outer is somewhat the larger.

The fractured surface of the inner fragment is slightly concave from before backward, and is a little convex from above downward and inward. That of the outer fragment corresponds.

Each fractured surface is smoothly polished, and is covered with a thin layer of cartilage, which is distinctly lighter in color than that which invests the normal articular surfaces of the bone.

The lower articular surface of the radius presents three articular facets instead of two. Of these the inner is the normal quadrilateral surface for articulation with the semilunar. The outer two occupy the triangular space on which the scaphoid rests, this space being subdivided by an outer posterior ridge, which corresponds to the fracture in the scaphoid.

The plainly-marked differences in the articular cartilage investing the various surfaces of the fragments would indicate an acquired condition rather than a congenital increase in the number of the carpal bones. The absence of any evidences either of remote lesion in the soft parts or of inflammatory reaction warrants the assumption that the fracture was simple rather than compound.

The man, probably, suffered a traumatism inflicted upon the wrist, and did not allow the joint to be confined. The non-union was the result of constant motion.

I do not think it probable that this condition could be recognized without incision. Positive diagnosis could rest only on independent mobility of the fragments, and it would be most difficult to obtain this evidence.

The specimen is in the Museum of the New York Hospital.

Case IV. *Angio-sarcoma of the humerus; amputation at shoulder; death.*—D. M., a man of twenty-one years, presented himself at the Outpatient Department of the New York Hospital, December 1, 1889, seeking relief for a swollen and painful shoulder.

He stated that he had fallen forcibly on the shoulder some four weeks previously, and that the accident was followed by pain, swelling, and disability, for the relief of which liniments had been applied.

Examination revealed a diffuse swelling of the left shoulder, extending from the origin of the deltoid half way to its insertion, and limited anteriorly and posteriorly by the axillary folds. The joint was the seat of almost complete disability. On pressing the thumbs well up into the axilla, the head and tuberosities of the humerus could be grasped. An assistant was asked to rotate the shaft of the humerus, and when this motion was made the head and tuberosities remained stationary. This rotation elicited a diffuse bony crepitus. There was no noticeable deformity other than that occasioned by the swelling.

Diagnosis of fracture through the surgical neck of the humerus was made, and the limb was enveloped in a plaster-of-Paris splint from the wrist to the shoulder, with a spica about the latter.

Three days after the application of the splint the patient complained of very severe pain in the shoulder. The splint was removed, and it was found that the swelling had considerably increased.

The splint was re-applied, but continuation of the swelling again necessitated its removal.

Two weeks after the patient came under my observation the enlargement of the shoulder was distinctly fluctuating. An exploring-needle was introduced and withdrew a fluid which microscopic examination showed to be pure blood.

During the following week the shoulder increased in size with considerable rapidity, and he was referred to the ward-service of the Hospital, where Dr. R. F. Weir, Attending Surgeon, made an exploratory incision, and found a large cavity filled with fresh and clotted blood, and fragments of bone loosely attached by periosteum. The upper extremity of the humerus, to the extent of about three inches, seemed to be wanting, a shell of bone alone representing the humeral head in the glenoid cavity.

The surfaces were thoroughly scraped with a sharp spoon, and fragments of tissue were subjected to microscopical examination, but no malignant elements were found therein.

During the week which followed the curetting the growth rapidly increased in size. The wound gaped, the skin was everted, and the protruding granulations bled profusely when irritated.

The patient developed a febrile movement, and the pulse became rapid and feeble.

On January 7th amputation at the shoulder-joint was decided upon, and was performed in the usual manner, but the patient succumbed to the shock of the operation and died shortly after its completion. The specimen was examined microscopically by Dr. F. Ferguson, pathologist to the hospital, who found it to be an angio-sarcoma of the humerus and surrounding tissues.

Upon the first study of the case I thought it probable that the man had sustained a fracture through the surgical neck of the humerus at the time of his original injury, and that the development of the sarcoma was consequent upon the traumatism; but after perusal of the literature of the subject, and especially after hearing the comments which followed the narration of the case before the Surgical Section of the New York Academy of Medicine, I think it more probable that the angio-sarcoma had existed for a considerable period without occasioning symptoms, and that the fracture took place through previously weakened bone.

Case V. *Lympho-sarcoma of neck.*—F.E., a stoutly built, robust man of thirty-seven years, applied for treatment at the out-patient department of the New York Hospital, May 4, 1889, suffering from a swelling of the neck, which had existed for several months. His previous personal history was good. He had never suffered with serious illness, and there were no evidences of specific or of tubercular taint.

In his work as the driver of an ice-cart he had been in the habit of lifting heavy cakes of ice, and he remembered that seventeen months previously he had severely strained the muscles of the back and neck while attempting to lift an unusually heavy weight from the ground to his wagon. Shortly after this unusual exertion he noticed small lumps on either side of the neck. These were painless, and he gave them but little thought until their increasing size led him to consult a physician, who prescribed internal remedies.

The medication did not, however, effect a diminution in the size of the lumps, and they rapidly increased in extent until they reached the dimensions which they presented when he first came under my observation. At this time the neck was

Fig. 5.

the seat of a hard, irregular swelling, which reached from the median line posteriorly to the symphysis of the jaw on the left side and to the middle of the body of the inferior maxilla on the right. It extended to the lobes of the ears above, and to the clavicles below (see Figs. 5 and 6).

Fig. 6.

It was made up of nodular, rounded masses, fused and immovable. The skin over these was congested and adherent. Hearing was diminished on each side. The neck measured twenty-three and a half inches in circumference. The floor of the mouth

was slightly invaded. The pharynx was free and there was neither dysphagia nor dyspnœa.

Examination of the body showed no other glandular enlargement. The spleen was normal in size. The specific gravity of the urine was 1035 and it contained a trace of sugar. Microscopical examination of the blood was negative in result. His general health was good. The size and character of the growth precluded the thought of operative procedure. Arsenic and iron were administered internally.

The growth steadily increased, and on July 10th the neck measured twenty-seven inches in circumference. He began to lose flesh and strength and rapidly emaciated.

Hard nodules appeared on the shoulders and chest, he began to be troubled with cough and dyspnœa, and gastric disturbances developed.

He sank progressively, and died about September 1st, some four months after I first saw him. An autopsy was not obtained.

Although the diagnosis of lympho-sarcoma lacks microscopical confirmation, yet the clinical aspects of the case would seem to warrant the belief that it is a reasonable assumption.

CLINICAL MEMORANDA.

OBSTETRICAL.

A Case of Extensive Dropsy during Pregnancy.—The following case is reported because of its comparative rarity. A primipara, seven months pregnant, was suffering from dropsy of the lower extremities and of the external genital organs. The legs and feet were swollen to an enormous size. The vulva was extremely œdematous, particularly the labiæ minoræ, which were as large as a hand, translucent, and extremely tender on pressure. The urine was scanty and albuminous. Rest in bed and the internal use of Epsom salt and cream of tartar rapidly reduced the effusion in the legs but had not the slightest effect on the swollen genitalia.

After persisting for a few days I punctured the organs with excellent results, the labiæ diminishing to almost normal size. Patient was then put upon tincture of the chloride of iron, and was apparently doing well. About five days after this I was summoned, found her in labor and delivered her of twins, one of which died in a few hours; the other is still living. The patient made a rapid and complete recovery.

Lusk speaks of six cases of dropsy in pregnant women treated by him, in which miscarriage followed puncturing the labiæ. Whether labor was brought on by the reflex effects of the operation or by the condition that caused the œdema, is a question on which I desire an expression of opinion. J. E. Covey, M.D.

Lexington, Illinois.

MEDICAL PROGRESS.

Treatment of Eczema.—According to Pick, in a recent paper before the German Dermatological Society (*Medicinische-chirurgische Rundschau*, July, 1890), the indications in the treatment of eczema are, first, protection of the skin from external irritants, and secondly, by means of antiseptics, prevention of local infection. In the earlier (dry) stages of the disease these indications are fulfilled by the use of sublimated gelatin prepared as follows:

R.—Refined gelatin . . 7½ drachms.
Distilled water, a sufficient quantity.

After standing for some hours this is heated until completely liquefied and is then evaporated to 2½ ounces. Then add,

Glycerin . . . 6½ drachms.
Corrosive sublimate . ¾ grain.

Before using, the gelatin must be melted by gentle heat in a water-bath, and it should be applied with a soft brush.

For the moist and vesicular, as well as the chronic form with more or less thickening of the skin, a permanent application of salicylic acid and soap should be used. The following is the formula used by Pick:

R.—Liquefied soap plaster . 3¼ ounces.
Salicylic acid . . . 75 grains.—M.
Spread on soft cloths.

This may be rendered more adhesive by the addition of olive oil, thus:

R.—Liquefied soap plaster . 2½ ounces.
Olive oil . . . . 5 drachms.
Salicylic acid . . . 37 grains.

The plaster should be cut in strips so that it may be closely applied to the diseased parts. If there is much secretion the plaster should be removed on the third or fourth day, but the subsequent dressings may remain in place eight days or longer. After the amount of secretion has been reduced, the sublimated gelatin may be used as in the dry form of the disease.

Lysol: a New Antiseptic.—Gerlach writes of the new coal-tar product, lysol, that it surpasses creolin and carbolic acid in germicidal powers; that it is less poisonous than either creolin or carbolic acid; that its composition is constant; that it is soluble in any proportion of water, and that even weak solutions are strongly antiseptic. For the treatment of wounds, Gerlach considers that a 1-per-cent. solution is sufficiently strong, and that for internal use solutions of half this strength are sufficient. —*Centralblatt f. d. Gesammte Therapie*, July, 1890.

Treatment of Chronic Hypertrophy of the Spleen.—Dr. Mosler, in the *Wiener med. Wochenschrift*, argues against extirpation of the spleen as a method of treatment in leukæmia. The chief danger is the tendency to hæmorrhage in such patients. The difficulty in deciding whether in any given case the condition is one of simple hyperplasia or a serious disease of the blood is also against the propriety of operation. In such cases Dr. Mosler first tries parenchymatous injections of a 2-per-cent. solution of carbolic acid, and then a mixture of one part of Fowler's solution and ten parts of distilled water. An ice-bag is applied to the spleen before injection, and owing to the contraction of the splenic muscles, the amount of blood contained in the organ is diminished. Ice-bags are also applied to lessen pain and prevent in-

flammation. This method, as well as injections of extract of ergot and sclerotinic acid, has frequently been employed by Mosler and others. In one case Dr. Mosler had the opportunity of examining the anatomical conditions of the spleen after injections of Fowler's solution. The capsule was found wrinkled and thickened, presenting patches over the thickened parts. The connection of those conditions of the capsule with the injections was indisputable. Dr. Mosler does not ascribe the diminution of the organ to the mechanical irritation produced by the injections, but rather to a direct influence on the spleen. He recommends great care in the use of the parenchymatous injections. Encouraged by these favorable results, Dr. Mosler tried these methods of treatment in the hypertrophy of leukæmia, and here also obtained considerable decrease of the organ. The subjective disturbances due to the hypertrophied spleen were thus lessened, and the moral impression made on the patient by the active treatment was also of value.—*British Medical Journal*, July 5, 1890.

Iodoform Emulsion in the Treatment of Cold Abscesses.—In the Polish journal *Gazeta Lekarska*, Dr. R. Jassinski reports the results he has obtained in the treatment of cold abscesses with iodoform emulsion. He opens an abscess only when it has become "residual," that is, when the primary focus in the vertebral column has healed or is separated from the abscess cavity. He has used iodoform emulsion in eighty-six cases, with the following results: A certain number of abscesses healed after a single injection, others after two or more injections. In 11 cases the abscess burst spontaneously after injection, and much pus, mixed with emulsion, escaped. Healing occurred without further surgical interference. In 19 cases aspiration was impossible owing to blocking of the trocar; the opening was therefore dilated, and the cavity washed out with a 3-per-cent. carbolic acid solution. Iodoform emulsion was then injected, and the wound stitched up. Occasionally a drainage-tube had to be inserted, and the injection frequently repeated. Dr. Jassinski has never seen symptoms of poisoning, though he has injected 180 grammes of a 10-per-cent. iodoform emulsion at once.—*British Medical Journal*, July 5, 1890.

Treatment of Lupus.—Mr. H. G. Brooke suggests a preliminary treatment in lupus vulgaris which he states (*British Journal of Dermatology*) considerably reduces the field in which operation is necessary, involves no pain, and requires, in most cases no suspension of work or of ordinary habits. The formula for the application he uses is as follows, this being the limit as to strength:

℞.—Oleate of mercury (2½–5 per ct.) 1 ounce.
Salicylic acid . . 10 to 15 grains.
Ichthyol . . . . 15 minims.
Oil of lavender, a sufficient quantity.

In every case it is better to begin with the smaller proportions, and the skin must not be broken by the application. If it becomes sore and threatens to break, the ointment must be diluted with pure lard. The ointment should be rubbed in ten minutes in the morning and twenty in the evening, and kept on during the intervening time. The effects are claimed to be most excellent. In some few cases the above ointment has been curative, but it produces its best effects in those in whom there has been no previous surgical interference. Its action upon deeply embedded nodules, lying among the fibrous meshes of old sores is not so marked, although it prevents or retards further growth.—*St. Louis Medical and Surgical Journal*, July, 1890.

Application for Fissured Nipples.—*The American Practitioner and News* quotes the following prescription for the treatment of fissured nipples:

℞.—Salol } of each . . . 1 drachm.
Ether }
Cocaine hydrochlorate . . 2 grains.
Collodion . . . . 5 drachms.—M.

Prescription for Malaria.—The following is used by Bacelli in the treatment of malaria:

℞.—Sulphate of quinine . . 45 grains.
Tartrate of iron and potassium 105 "
Distilled water . . . 9 ounces.
Fowler's solution . . 24 minims.—M.
One teaspoonful from one to three times daily.
—*Centralblatt f. d. Gesammte Therapie*, July, 1890.

Nitroglycerin in the Treatment of Opium-habit.—In the Paris letter to the *Lancet* of June 14, is reported the success of Dr. Oscar Jennings in the management of the opium-habit. He presented to one of the medical societies a member of the profession who had been addicted to the drug for twenty years, and who had repeatedly failed in his efforts at self-cure. Dr. Jennings had him under treatment three weeks, and ten days had elapsed without a return to the use of the drug. There remained considerable prostration, but none of the craving that leads to the resumption of the habit. Dr. Jennings, in his treatment of such cases, relies largely on the heart-tonics, especially nitroglycerin, in the form of the compound tabloids, and galvanization of the head with baths of hot water and of hot air. The withdrawal of the opiate is gradual, occupying a period of from two to three weeks, the latter period being commonly required in cases of long duration. The compound tabloids of trinitrine contain nitroglycerin $\frac{1}{100}$ grain, amyl nitrite ¼ grain, capsicum $\frac{1}{50}$ grain, and menthol $\frac{1}{50}$ grain each.

Fatal Case of Schoeler's Iodine-injection Treatment of Retinal Detachment.—Dr. Gelpke (*Centralblatt f. Praktische Augenheilkunde*) reports a fatal result following Schoeler's injection-treatment of retinal detachment. The patient was a male of sixty-six years, of robust build, in whom the detachment took place in an eye, formerly perfectly healthy, without known cause. Three drops of the tincture of iodine were injected into the vitreous chamber, after the method described by Schoeler, with rigid antiseptic precautions at every step of the procedure. Despite these precautions an infectious purulent choroiditis sprang up in the eye operated upon, and two days later this was succeeded by a purulent meningitis. Death took place on the sixth day after the operation.

Therapeutic Uses of Aniline.—As is well known, Professor Kremianski, of Kharkoff, has for some years

advocated the employment of aniline as an inhalation in phthisis because of its great germicidal power. He continues to practise this method, as he says, with considerable success, and has just published a new brochure on the subject detailing an interesting recent case in which, he states, it proved most beneficial, and he describes a new and more convenient form of inhaler. His methods have hitherto found but little general favor, it having been stated by some observers that the inhalation of aniline is very dangerous. Dr. Kremianski has, however, always denied this, declaring that aniline, if pure, is practically non-poisonous, and this view has been confirmed by the researches of Professor Stilling, of Strasburg, who has just published an important work on the subject of aniline colors as antiseptics and their employment in practice. He finds that the most antiseptic of these colors is the violet, which is known to microscopists as methyl-violet. A solution of this of the strength of 1 in 1000 can be injected under the skin of a guinea-pig to the amount of 5 drachms, or more, without harm to the animal. Half that quantity, however, if injected into the peritoneal cavity, proves fatal, the viscera, and especially the kidneys, with the exception of the Malpighian corpuscles, being colored blue. A few drops of the solution instilled into the eyes of rabbits colored the conjunctiva, but left the cornea—if this were uninjured—unaffected, the coloration disappearing the next day. Professor Stilling then employed this solution with marked success for the treatment of many eye and other diseases, including scrofulous ulcers of the cornea, conjunctivitis, eczema of the lids, parenchymatous keratitis, serous iritis, disseminated choroiditis, sympathetic ophthalmia, whitlow, varicose ulcers of the leg, etc. A pure form of methyl-violet for surgical purposes is now manufactured under the name of pyoktanin. It is only right to add that Dr. Mauthner, of Vienna, has just published a statement that he has been quite unsuccessful in his trials of this substance in a number of eye cases similar to those in which Professor Stilling has recorded such favorable results.

Professor Ehrlich and Dr. Lippmann have found that methyl-blue, when perfectly free from chloride of zinc and all other impurities, is a valuable and safe remedy for relieving pain of various kinds. They have given as much as fifteen grains daily in gelatin capsules without producing any toxic symptoms. The usual doses were from a grain and a half to four grains internally, and one grain hypodermically. The remedy was employed in twenty-five cases of painful nervous affections, and rheumatism of the muscles, tendons, and joints, and in every case it proved more or less efficacious. In two cases of migraine, also, it was very successful. In many ways this substance appears to act similarly to antipyrine, over which it has the advantage of cheapness, and of being painless when given hypodermically.—*Lancet*, July 5, 1890.

Prescription for Constipation in Infants.—According to the Paris correspondent of the *Archives of Pædiatrics*, the following is a prescription used by DR. FERRAND:

R.—Manna . . . 12½ drachms.
Calcined magnesia } of each, 2½ "
Sublimed sulphur }
White honey . . . 7½ " —M.

One or two tablespoonfuls in a cup of hot water.

Thymol Tooth-powder.—The *American Practitioner and News* quotes the following:

R.—Precipitated chalk . . 7½ ounces.
Powdered soap . . . ½ ounce.
Saccharin . . . . 5 grains.
Thymol . . . . 7½ "
Camphor . . . . 15 "
Vanillin . . . . 2½ "
Oil of rose . . . . 3 drops.

Rub the camphor and thymol together in a mortar and warm gently until the mixture is liquefied. Then add the chalk in small portions, reserving about half an ounce. Next add the other ingredients, the perfumes having been mixed with the remaining half ounce of chalk.

The Transmission of Typhoid Fever by the Air.—DR. BORDAS (*La Revue Médico Pharmaceutique*) has instituted experiments to determine the relation between the humidity of the atmosphere and the transmission of the typhoid bacillus. A current of dry air, completely devoid of germs, was conducted through a vessel containing a beef-broth culture of the bacillus and into a second vessel containing sterilized beef-broth. The second vessel remained sterile. The result was the same when a dry atmospheric current was passed over pumice stone saturated with a culture of the typhoid bacillus. When moist air was passed through the same vessels a very different result was obtained. The sterile beef-broth culture was found, after the lapse of a quarter of an hour, to be thickly planted with the bacilli.

In nature this state of humidity is supplied by mist or fog, and statistics show an increase of typhoid fever in Paris during the months of October, November, December, and January. The most general mode of propagation of typhoid fever is by the contamination of the soil or water, but there are cases in which it is manifested by pulmonary localization. The germ may penetrate into the bronchial system in spite of every means of defence possessed by the organism. Metchnikoff's studies prove that the lungs are a phagocyte battle-ground. In typhoid infection, due primarily to pulmonary lesion, it would seem that the phagocytes of the lungs are ordinarily sufficient to prevent the development of the infectious germ, and that contagion by means of the air can take place only when the macrophagic cells cease to offer an obstacle to the invasion of the microbe.—*Abstract of Sanitary Reports*, July 11, 1890.

Nitrate of Cocaine in the Treatment of Urethral Diseases.—LAVAUX thinks that nitrate of cocaine should replace the hydrochlorate as a urethral anæsthetic previous to the application of nitrate of silver. The nitrate may be prepared by pouring a solution of the hydrochlorate into a solution of nitrate of silver. An insoluble precipitate of chloride of silver falls, and nitrate of cocaine remains in solution.

The following formula for an injection to be used in the treatment of gonorrhœa is given:

R.—Nitrate of silver } of each 15 grains.
Nitrate of cocaine }
Distilled water . . . 1½ ounces.—M.

The injection of this solution is said to be painless.—*Journal of Cutaneous and Genito-urinary Diseases*, July, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

ANTIPYRINE IN OBSTETRICS.

THERE are but few painful conditions in which antipyrine has not been used, and while its haphazard employment has no doubt done much harm and has led to its indiscriminate use by the laity, yet this widespread use has brought to light many facts as to its therapeutic value. The well-known analgesic property of the drug naturally led to its employment to relieve the pains of labor, and it was not long before reports were published in various parts of the world which unfortunately have been of such contradictory character as to make it of doubtful value for the relief of the pains of childbirth.

In the *Revue Générale de Clinique et de Thérapeutique*, M. MISRACHI reports the results of his investigations to determine the indications for antipyrine in obstetrics, and by closely studying his cases has thrown much light upon the subject. An analysis of the facts offers a very satisfactory explanation of the numerous contradictory reports. It is well known that a certain amount of pain during labor is physiological and normal, and in the cases in which antipyrine has been employed with success it is noteworthy that the pains were invariably aggravated. Thus, its successful use has been reported in cases of miscarriage, accompanied "with most violent pains." Another observer gave it with success to a primipara long in labor, who "screamed loud enough to be heard in adjoining rooms," and another to a patient "in labor for two days without any dilatation of the cervix." M. Misrachi administered antipyrine to thirty women during labor, and found it efficient for the relief of pain in only nine of the cases. In five of these the lumbar pains were intense; in one there was tetanic contraction of the uterus; in two excessive rigidity of the cervix, and in one great nervous excitability. In four of the cases premature discharge of the liquor amnii had occurred, and in all, the pains had lasted for a long time—six, seven, twelve, eighteen, and in some seventy-two hours, with only slight dilatation of the os. In these nine cases the drug acted most happily. The pains were relieved, the nervous excitability calmed and the tetanic contraction of the uterus and rigidity of the cervix disappeared. In the remaining twenty-one cases, which were normal in every respect and in which the drug was given merely as an experiment to determine its action upon normal labor pains, it gave no relief whatever.

These observations seem to prove conclusively that antipyrine should not be considered an obstetric anæsthetic to be used in all cases; that when labor is normal it is useless and not to be compared to ether or chloroform; but that it is of value in the treatment of certain painful complications of labor. Every obstetrician meets with cases in which the contractions of the uterus are vigorous but the accompanying pain so intense that it reflexly interferes with the contractions, rendering them inefficient and irregular, the patient meanwhile continuing in her struggling efforts. In such cases antipyrine is most efficient. It relieves the excessive pain and favors a return of effective uterine force. Its employment is therefore indicated when labor is tedious; when there exists an exaggerated nervous susceptibility to pain; when the liquor amnii has been prematurely discharged; when there is rigidity of the cervix, spasmodic contraction of the os or of the body of the uterus. There have been many such cases reported in which antipyrine has proved more efficient than the usual treatment with opium, belladonna, warm injections, chloral, or quinine.

M. Misrachi also confirmed by his observations a fact that had been noted before by others; namely, that antipyrine should not be employed to relieve the pain of the second stage of labor. At this

time, when the pain is due to compression and to the great distention of the genital canal, antipyrine, like opium and chloral, is of no service. The anæsthesia of ether or chloroform is required. These limitations to the employment of antipyrine do not, however, entirely remove its usefulness in obstetric practice.

Besides the relief it affords to excessive pain during the first stage of labor, it has given very good results in the treatment of false pains, threatened abortion, and after-pains. A woman pregnant about eight months was seized with pains analogous to true labor pains. Examination two and three hours later revealing no dilatation of the os, antipyrine was given and the pains promptly disappeared.

In those cases in which throughout pregnancy there occurs at each presumed menstrual epoch a slight hæmorrhage and considerable pain, antipyrine has been used with great success. M. Misrachi mentions a case of this kind, in which it succeeded after opiates and prolonged rest had failed. Favorable results have been obtained from its employment in the treatment of threatened abortion and miscarriage, but they are, as would be expected, by no means constant. In any case of abortion or miscarriage it is usually difficult to decide whether it is avoidable or inevitable, and if the ovum is partially or completely separated antipyrine, of course, fails, just as every remedy uniformly fails. Nevertheless, M. Misrachi employed it with success in cases where the usual treatment failed and thus avoided the unfortunate necessity of converting a threatened miscarriage into an inevitable one. In connection with this it is interesting to note the results of the use of antipyrine in the treatment of a condition somewhat analogous to threatened miscarriage; namely, placenta prævia. Of two cases reported, in one it controlled the bleeding three times, at the fourth, sixth, and seventh months, respectively. In the other a slight hæmorrhage had occurred at the sixth month, and at the end of the eighth month there were profuse hæmorrhage and uterine contractions, and the os dilated to the size of a silver dollar, the placenta being centrally implanted. Forty-five grains of antipyrine (fifteen grains every half-hour) diminished the contractions and arrested the hæmorrhage. The delivery was completed six hours later with no bad results. Although, as M. Misrachi remarks, these two cases prove nothing, since it is well known that the hæmorrhage of placenta prævia in the course of pregnancy often ceases spontaneously, especially when the head engages, yet it is interesting to note these results with antipyrine, as it would be a decided therapeutic advance if it could be shown to have uniformly so good an effect.

The very numerous favorable reports indicate that antipyrine is of undoubted value in the treatment of after-pains. M. Chauppe was the first to call attention to its value in cases when the pains are due to ergot. M. Negri announces that in his clinic it has replaced all other remedies for after-pains, and M. Misrachi concludes from his own observations and those of his colleagues at the Salonique, comprising hundreds of trials, that it succeeds in 95 per cent. of cases. In his large experience with the drug in obstetrics he has not met with a single case in which it has produced untoward symptoms. The numerous reported cases of antipyrine poisoning are doubtless due to personal idiosyncrasy, and in obstetrics, as elsewhere, this of course cannot be foreseen. M. Misrachi generally administers fifteen, thirty, or forty-five grains at intervals of one hour, decreasing the intervals to a half-hour in urgent cases. He found that ordinarily thirty grains were sufficient. When a tendency to vomiting exists he prefers enemata. Two or three may be given, composed of thirty grains of antipyrine dissolved in four ounces of water containing five drops of laudanum.

REVIEWS.

Cyclopædia of the Diseases of Children, Medical and Surgical. By American, British, and Canadian Authors. Edited by John M. Keating, M.D. Vol. III. 8vo., pp. 1370. Philadelphia: J. B. Lippincott Company, 1890.

Many of the remarks we had occasion to make in our reviews of the preceding volumes of this work are also applicable to Volume III. The same accurate judgment is shown by the editor in his selection of authors best fitted for the articles which they have contributed, and with few exceptions the contributors have done their work conscientiously and well.

Part I., on Diseases of the Digestive System, opens with a thirty-page article by Pepper on Functional Disorders of the Stomach. A large part of this is naturally devoted to a discussion of dyspepsia. Treatment is very fully entered into and numerous, somewhat conventional, prescriptions are given. Hare follows with a carefully worked-up paper upon Diseases of the Stomach, the most exhaustive portion of which is that upon dilatation of the stomach, a condition that, we have reason to believe, is frequently overlooked. An excellent cut taken from a photograph is given (unfortunately

entitled a *distended* stomach) showing how great the dilatation may be.

Next are more than one hundred pages by Holt upon the Diarrhœal Diseases, Acute and Chronic. This is one of the longest papers in the volume, and is undoubtedly the most valuable contribution upon the subject in the English language. It is illustrated by sixteen "process"- and wood-cuts of the pathological anatomy of infantile diarrhœa. Pathologically, Dr. Holt divides diarrhœas into: (1) Acute desquamative catarrh, embracing the acute cases with no lesions except loss of the superficial epithelium; (2) acute catarrhal inflammation, other lesions than the loss of epithelium being present; (3) acute inflammation with ulceration of the lymph nodules; (4) acute croupous inflammation; and (5) chronic inflammation. We can see no reason why the first two divisions should be separated, Dr. Holt himself intimating that the second is only an advanced stage of the first. Clinically the author classifies the diarrhœas thus: (1) Simple diarrhœa; (2) acute mycotic diarrhœa, including (*a*) acute dyspeptic diarrhœa and (*b*) cholera infantum; (3) acute entero-colitis; (4) chronic diarrhœa, including (*a*) primary cases due chiefly to depraved constitution and continued improper feeding, and (*b*) secondary cases in which the chronic disease follows acute entero-colitis. In the treatment of simple diarrhœa, Dr. Holt advises a full dose of castor oil followed by an opiate, and almost complete abstinence from food for twenty-four hours. In acute dyspeptic diarrhœa he gives castor oil or calomel, and when the bowels have been thoroughly cleared out he prescribes bismuth subnitrate, "two or three drachms daily to a child a year old." Naphthalin, after a thorough trial, he has concluded is greatly inferior to bismuth.

Booker contributes an interesting, though decidedly prolix, article upon the intestinal bacteria of children. Twenty pages devoted to this subject seem an unnecessarily large number, and a few illustrations would increase the value of the article. Excellent advice is given upon the management of constipation in children by Earle, who is evidently thoroughly familiar with the subject of which he writes. Tabes Mesenterica is discussed by Jacobi in his usual readable and instructive manner. Much of the article is devoted to showing that the pathological anatomy of tabes mesenterica "is by no means the same in all cases, and that the term itself should disappear from our indexes or be recognized as merely a convenient expression for a complex of more or less similar symptoms." To those who are not familiar with the etiology and life-history of intestinal parasites we commend the concise paper on the subject by Councilman. Hernia in children is considered in a very practical manner by William J. Taylor. Next follows a very valuable paper by Keen on Intestinal Obstruction, a subject on which he is eminently qualified to write. In the article on Peritonitis, by Ashby, we are surprised at the statement of the author that in a fair proportion of cases of tubercular peritonitis under medical treatment recovery may be looked for. To us, supposed recovery from tubercular peritonitis as from tubercular meningitis means in most cases error in diagnosis. Fenger's article on Perityphlitis, Paratyphlitis, and Perityphlitic Abscess, reveals a large amount of research, but is disappointing in that it is to a great extent a reflection of others' views with but few of the author's own opinions.

Congenital Abnormalities of the Intestines—Malformations, Injuries, and Diseases of the Rectum and Anus, are handled in a masterly manner by Wharton, and the same may be said of the articles by Packard on Colotomy and by Senn on Diseases of the Pancreas and their Operative Treatment. A brief article by Chapin, on Functional Disorders of the Liver, Jaundice, and Diseases of the Ducts and of the Portal Vein, is followed by sixty-six pages on Enlargements of the Liver in Children, by Musser. The latter paper includes a description of affections which simulate enlargement of the liver, namely, congestion, fatty infiltration, amyloid disease, hydatid disease, abscess, and tumors. Contractions of the Liver, including both hypertrophic and atrophic cirrhosis, are considered by Hatfield.

In Part II., Diseases of the Genito-Urinary Organs, the most valuable contributions are those of Goodhart, on Acute and Chronic Bright's Disease; Hunt, on Vesical, Urethral, and Preputial Calculi; Vander Veer, on Diseases of the Bladder; the Editor of the *Cyclopædia*, on Diseases of the Uterus, Vagina, and Vulva; and Kelly, on Diseases of the Ovaries and Tubes. Next follow eighty-four pages on Diseases of the Blood and Blood-making Organs, by Griffith. No pains have been spared by the author in making this article complete. Descriptions and illustrations of the various apparatus for estimating hæmoglobin and counting corpuscles are given with full directions upon the method of using. A somewhat original and very excellent classification is in itself evidence of the care given to his work by the author.

Part III., Surgery, contains four excellent articles—Minor Surgery and Emergencies in Children, by Dulles; Plastic Surgery, by Morton; Wounds, by McCann; and Anæsthetics and Anæsthesia, by Allis. We regret that in the last-named article the author shows so strong a preference for chloroform as an anæsthetic. True, he recommends it with this qualifying sentence, "on the condition that it shall be properly administered." Doubtless chloroform administered carefully is safer than ether administered recklessly, but there seems no longer reason to doubt that, if given with equal care, fewer deaths will occur from ether than from chloroform. The very fact that the latter demands more care is an argument in favor of the former.

We have already so far exceeded the space allotted to us that we can only briefly mention Part IV., Diseases of the Osseous System and of the Joints. The most valuable of the articles in this part, perhaps because on the most important subjects, are those of Bradford and Brackett, on Club-foot; A. Sidney Roberts, on Pott's Disease; Poore, on Diseases of Major Articulations; and Gerster, on Deformities of Bone—Osteoclasis and Osteotomy.

The volume deserves a much more extended notice than it has been in our power to give it. There is little or nothing to be said in criticism; editor, authors, and publishers have done their work in a manner that disarms the critic.

Marine-Hospital Service.—The United States Senate has passed a bill increasing the salary of the Surgeon-General of the Marine-Hospital Service to $6000 per annum.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 15, 1890.

The President, Alfred L. Loomis, M.D., in the Chair.

During the past few years various efforts have been made to utilize the telephone and microphone in connection with the study of physical diagnosis, but without very flattering success; for, delicate as these wonderful instruments are, they have not been able, as yet, to differentiate those nice distinctions in the quality of sound, which are so full of meaning to the practised ear of the diagnostician. One of the latest attempts in this direction has been made by Dr. L. L. Seaman, who presented the result of his labors to the Academy of Medicine, in an instrument which he called

THE AUSCULTATORY PERCUSSOR.

The apparatus may be said to consist of the well-known Cammann's binaural stethoscope with a large wooden chest-piece, connected with a mechanical device for performing percussion simultaneously with auscultation. The percussor works through a slot in the side of the chest-piece, and strikes a thin metal pleximeter situated in the centre of the "field" of the stethoscope. The blow of the hammer is delivered vertically, and its force can be readily regulated, thus giving more accurate results. Another source of error is eliminated by having the pressure of the pleximeter against the chest constant. Permanent records of the examinations made with this instrument can be obtained by attaching it to Edison's phonograph; and these records when reproduced by the phonograph might be utilized for class instruction in physical diagnosis. Dr. Seaman gave a demonstration of its powers in this direction, by so attaching it to a phonograph that fourteen persons could listen simultaneously to the reproduced sounds.

The remainder of the evening was devoted to a discussion of the advances made in

SPINAL SURGERY.

It was opened by Dr. Robert Abbe, who reported eight cases. From a study of these cases, he concluded that the pressure of the displaced bone in fracture of a vertebra is of secondary importance, unless the arch is driven in by a blow. There is usually no marked deformity of the canal; and if the fracture occurs at or below the first dorsal vertebra, the crushing does not as a rule destroy the nerves. In efforts to relieve these cases by operative means, one is confronted by a difficult problem—*i. e.*, how to connect the lower segment of the spinal cord with the upper portion, when there is a gap of half an inch or more. Dr. C. L. Dana has suggested the ingenious expedient of transplanting the cut nerve-roots into lower roots, or into a lower segment of the cord.

In discussion, Dr. John A. Wyeth commented upon the frequency with which the injury occurs at the eleventh dorsal vertebra, and spoke of some of the difficulties he had encountered in this line of work. He related the history of one case of fracture of this bone, in which paraplegia was instantaneous, and persisted for about eight months, when the speaker partially relieved the patient by operation. When the canal was opened the dura was so distended with fluid as to project through the wound, and when punctured by the operator a stream of spinal fluid was forced upward for a distance of six or eight inches. Two and a half inches of the cord was exposed, and inflammatory lymph was found between the dura and the cord. Adhesions were broken up and the wound closed. Sensation returned at once throughout the entire leg, and motion was restored to the two great toes. Dr. Wyeth thinks that the field of spinal surgery is just beginning to open up to us, and he believes that many of these unfortunate patients might be restored to usefulness, particularly those in whom the paralysis has been gradually produced by pressure in Pott's disease.

Dr. A. G. Gerster said that he had been particularly interested in those cases where the spinal marrow is divided in consequence of traumatism, leaving a more or less extensive gap. Reasoning from analogy, he thought that re-union of the divided ends of the cord would probably result in a restoration of function. These cases, he said, are so desperate that almost any measure which holds out any hope of relief is justifiable. He thought that in the future it might even be shown to be possible to remove the vertebra, and so enable the separated ends to be brought into apposition.

Dr. R. T. Morris was sceptical as to the benefits that would follow this procedure of suturing the cord, for experiments on animals have shown that ascending and descending degeneration begin immediately after section of the cord, and progress for days and even weeks. It is possible that the operation might prove successful if performed within a few hours after the receipt of the injury. The spinal cord cannot retract very much when divided, because of the spinal nerves. Nor does the proposal to remove the entire vertebra offer a solution of this problem; for even supposing it could be done, trouble would arise from the consequent crowding of the spinal nerves. In one case of gunshot injury to the spine at the level of the ninth dorsal vertebra, upon which he had operated, the patient suddenly found, about ten months later, that he could move the adductors of the left leg. This is an example of very late regeneration of the cord.

Dr. R. H. Sayre said that although many cases of Pott's paraplegia will recover without operation, he thought those cases which do not yield to other treatment within twelve months are suitable for operative interference.

Dr. B. Sachs said that the most suitable cases for operation are the recent ones, and those in which the symptoms subsequently improve, showing a probable obstruction to proper nerve conduction. Dr. Abbe, he said, deserves credit for showing that even tubercular cases might yield favorable results from operation. The speaker did not see any need of such extensive opening of the canal as had been described; for a careful diagnosis of the distribution of the paralysis in a given case would indicate the exact seat of the trouble, even to the very segment of the spinal cord which is involved. Although both of Dr. Abbe's cases of neuralgia were improved by operation, Dr. Sachs considered it an ex-

tremely radical measure to attempt operation upon the intervertebral spinal roots. Unless one has has good reason to believe that there is organic disease of the posterior spinal roots, it is well not to interfere.

Dr. Abbe, in closing, said that it is only in these exceptionally severe neuralgias that any sane man would think of operating. Mr. Bennett, of England, has recently reported a case in which he had divided the posterior roots of the lumbar and sacral nerves, intradurally, for intractable neuralgia of the leg. The wound healed and the patient was entirely free from pain for twelve days following the operation, when he died of apoplexy. The ascending degeneration which takes place after division of the posterior root, certainly obliterates the remnant up to the ultimate fibres of that root; and this, Dr. Abbe thought, should remove the pain. Operations on fractures of the spine are ordinarily useless; but he hoped that future experiments on animals would show us how to innervate the upper and lower portions—probably by transplantation of the roots, or some similar method. The removal of the entire vertebra, in view of its important surroundings, and the mechanical obstacles to be overcome, seemed too difficult a problem even for modern surgery.

CORRESPONDENCE.

VIENNA.

To the Editor of The Medical News,

Sir: When the Vienna faculty called Professor Krafft-Ebing to the university from Graz last fall they showed their wisdom, for his clinics are well attended and are constantly growing in favor. On Mondays and Thursdays he holds clinics on Mental Diseases and Insanity at the Insane Asylum; on Tuesdays and Fridays he lectures on "Legal Psychiatrie," illustrating the points by cases; and on Wednesdays he demonstrates "Selected Cases of Nervous Diseases." He shows many cases of the same disease together, thus presenting the clinical picture in all its forms and varieties—for example, he recently showed some twenty cases of tabes dorsalis. Krafft-Ebing is not a believer in the syphilitic etiology of tabes, and some of the men who were the most ardent advocates of this theory last year are becoming very reserved. He uses the suspension treatment for tabes, and in several cases has seen excellent temporary results, yet he does not consider it by any means a specific.

Dr. Salzer, the son of Professor Salzer the gynecologist, the brilliant first assistant at Billroth's clinic, has accepted a professorship at Utrecht, Holland, and leaves Vienna at the close of the present semester. He is a fine operator, and gave excellent courses in atypical operations, so that he is popular among the Americans here. Dr. Eiselsberg now becomes Billroth's first assistant. Professor Kahler is very ill with some nervous disease, and his first assistant, Dr. Kraus, has been delivering the lectures on internal medicine with marked success.

A few days ago, at Albert's clinic, we saw a case of traumatic contusion and laceration of the right kidney. The boy had been severely injured, was very anæmic, and had been passing blood with his urine for several days. There were great pain and marked dulness over the region of the right kidney. Operation for removal was performed. Albert prefers a long incision at right angles to the spinal column, beginning at about the posterior axillary line; and he opens the peritoneum in order to have plenty of room and light for operating. The kidney was found to be severely injured, its lower end was considerably lacerated, and nearly two pints of blood-clot and urine were removed. Now, a week after operation, the case is doing very well.

The surgery of the liver is progressing rapidly, and they quite often remove the gall-bladder for cholelithiasis. In a case at Albert's clinic Hochenegg removed a gall-bladder containing fifty-two gall-stones, and as the walls were carcinomatous, he examined the liver carefully for metastasis. He found but one metastatic deposit near the anterior border, removed it with the knife, sewed the peritoneum all around the wound, and finally sewed up the abdomen in such a manner that the wounded liver could be seen from without. The extirpated portion was one by one and one-half inches in size. It is now over nine months since the operation, and there seems to be no recurrence. The case is interesting because it is believed to be the first where a neoplasm was removed from the liver with good result.

There is much tuberculosis in Vienna, and the disease has even received the name of *morbus Viennensis* among medical men. Sarcoma is also alarmingly frequent, and it is now taught here that when sarcoma affects a limb the best treatment is early amputation. An immense experience and all statistics prove, says Professor Albert, that in nearly every case where sarcoma is removed, even by a very thorough operation, recurrence takes place either in the scar or near it, and a second operation though more thorough can avail but little. Finally amputation of the limb becomes a necessity, and it would have saved the poor patient much suffering if this radical operation had been performed at once.

Dr. Jahoda, Professor Salzer's first assistant, gives an excellent course in gynecology, and though he has been teaching only a few months the demand for a place in his course is so great that a man must apply months ahead. He takes but four men in his class. In all the Vienna clinics gynecological examination is made almost exclusively by the bimanual method, two fingers in the vagina, the other hand on the abdomen; and the use of the speculum for diagnosis is unusual. Examination per rectum is resorted to very frequently, and bringing the uterus down with a bullet forceps introduced into the vagina, it can be felt by the finger in the rectum. Treatment of fibroids by electricity has found some followers here, though the general opinion is strongly in favor of operation for most cases, and when one speaks of the dangers of laparotomy for fibroids they quote their brilliant record—less than 10 per cent. of deaths. In Salzer's clinic they now use the Lawson Tait method of perineorrhaphy almost exclusively, and report most excellent results.

In Nothnagel's clinics two instruments are in constant use which should be in the hands of all physicians, for they make the differential diagnosis of leukæmia, leucocythæmia, chlorosis, and pernicious anæmia almost mathematically certain. With the hæmocytometer the blood-corpuscles are counted, and the proportion of red to white established, and with the

"Fleischl hæmoglobinometer" the relative amount of hæmoglobin in the blood is found. A few drops of the patient's blood are sufficient for the examination. Dr. Lorenz, Nothnagel's assistant, showed us a case of tetanus. A week ago the man was severely injured in his right eye by an iron splinter from the hoop of a barrel. The cornea was torn and the iris prolapsed, and he was treated for nearly a week at Fuch's clinic. On Thursday they noticed there a slight trismus, difficulty in swallowing, and some stiffness in the legs. He was transferred to Nothnagel's wards, and on Friday morning showed the following symptoms: His mind was clear, there were no marked symptoms in the face, and chewing was quite easy; forward and backward motions of the head were limited, lateral motions free. It was hard for him to swallow liquids, and he took but little at a time, but the lips moved very freely. The muscles of the chest and arms were free, but a slight spasm could be detected in the pectorales and the muscles of the shoulder stood in more marked relief than normal. The diaphragm was movable and the breathing good. Attempting to raise the patient to a sitting posture at once produced opisthotonus. Sensibility of the entire skin was perfect, fever was absent, but there was profuse sweating on the face, chest, and limbs. Every few moments clonic spasms, in which the pains were intense, occurred. Two days later the patient died. There was no post-mortem rise of temperature. On section a broncho-pneumonia was found, but no changes in the nervous system save a few very small hæmorrhages in the cord, and the immediate cause of death was the pneumonia. In his lecture on Tuesday Nothnagel said: "Tetanus is an acute infectious disease, due to a bacillus, which has been thoroughly studied, has been cultivated in pure culture and inoculated, always producing tetanus. The bacillus can always be found in cases of true tetanus, and it is also frequent in garden soil and dust. It is probable that the disease is due primarily not to the tetanus bacilli, but to a toxine which is produced called tetanin or tetanotoxine, and this acts on the nervous centres. Frieder, of Berlin, has extracted tetanin from the bodies of cases of tetanus, and by its inoculation has caused the disease in lower animals even without inoculations of the bacilli. Death from tetanus occurs in 85 per cent. to 96 per cent. of the cases, and is brought on in one of three ways: by paralysis of the nerve centres, by suffocation from tetanic contraction of the muscles of respiration, or from complications, as in our case." Nothnagel's therapy is as follows: "Place the patient in a dark room, away from all irritation and noise, give large doses of morphine hypodermically, and great quantities of chloral and bromides by the stomach and rectum. Feed the patient well, by the stomach-tube if necessary." He considers physostigma less valuable than the bromides and chloral, and curara he thinks is useless, because it merely paralyzes the peripheral motor nerves, and does not affect the centres.

The system of promotion and of training men for didactic medicine in Vienna is peculiar. The student is required to give proofs of a thorough education, about equivalent to that of our colleges before he can be admitted to the medical school. The course in medicine is ten semesters or five years, and after graduation good scholars can serve for an additional two years in the various clinics, each of which admits about five men every year. During these two years they have splendid advantages, specially in surgery and gynecology, where they perform even capital operations. From the best of these operators or aspirants, as they are called, the professor selects his assistants, who may serve for six years. The assistant has almost complete charge of the clinic, can use the clinical material for teaching, and can thus gain valuable experience as a teacher, as well as make a good income. As the students are free to choose their instructors from a large number of assistants, of course merit and ability succeed best, and when the assistants become favorites their future is secure. They next become private docents, and then receive calls to other universities as extraordinary professor, and finally they reach the professorship "ordinarius." This thorough method of promotion is the secret of the fame of the Vienna teachers.

NEW ORLEANS.

Malarial Fevers. New Orleans Polyclinic. Medical Legislation. Arsenical Poisoning from Iced Sherbet.

To the Editor of The Medical News,

Sir: The warm weather and the large area of overflowed land in the State have not yet had any perceptible effect in increasing the usual amount of malarial fevers treated in Charity Hospital during the summer. Strange to say, Dr. Bruno, the pathologist of that institution, has not had Osler's and Councilman's success in finding the hæmatozoön of Laveran in the blood of many cases that he has examined.

Speaking of this institution recalls the fact that the existing laws give the Tulane University the sole privilege of using the wards for clinical purposes. As soon, however, as the session has ended the clinical professors take a vacation until the commencement of the fall session, and during the summer their places are filled by younger men, most of whom are members of the faculty of the Polyclinic. In a former letter the brief spring session of this institution was referred to, and as the work is essentially practical, the course could not be continued in winter unless the State Legislature granted to the Polyclinic the privilege to use the wards.

With a singular monopolistic tendency the Tulane University is antagonizing such legislation. The law has passed the State Senate, but in the lower house it is meeting with active opposition from the administrators of Charity Hospital, who are acting in behalf of the University. It seems unfortunate that, for no valid reason, a worthy educational institution may be deprived of what seems as much a right as a privilege.

The action of a Legislature in medical matters is notoriously uncertain, often opposing the enactment of what would be excellent sanitary laws. Only recently the coroner of New Orleans urged the passage of a bill that would do away with a coroner's jury; that would permit the employment of an expert chemist in cases of suspected poisoning, and would require coroners to make annual reports to the Governor. There were other minor sections relative to fees to coroners. Yet the act was so amended that when it passed the Legislature it was practically emasculated.

Dr. Chassaignac, president, and a committee from the

Orleans Parish Medical Society, have been before the Legislature to urge the passage of an act to regulate the practice of medicine, and there is reason to believe that such a law will be enacted. The law recommended by the Society provides, in the first section, that no person shall practise medicine in the State unless he possesses the qualifications required by the act. The second section demands a diploma from some medical college in good standing, and an examination in the different branches of medicine before the State Board of Examiners, who—the third section provides—are to be appointed by the Governor from the six different Congressional districts. The fourth section allows the members to grant a temporary permit until the next meeting of the Board; and the fifth section provides that the members shall be appointed for twelve years. Other sections provide that the Board shall meet at least twice a year; that it shall elect officers, who are authorized to administer oaths; that the District Court of each parish shall keep a record of certificates issued, and send a copy thereof to the State Board of Health; that an annual list of registered physicians shall be published; that compensation and travelling expenses shall be allowed members of the Board; that itinerant quacks shall be fined; that persons practising without a certificate shall be fined; that licences may be revoked for unprofessional conduct; that officers of government medical services shall be exempted from the provisions of the act, and that the expenses of the Board shall be paid from its revenues. The law essays to be comprehensive, and has been carefully considered by its advocates.

An effort was recently made to separate the local and the State functions of the Louisiana State Board of Health, by depriving it of jurisdiction over sanitary matters in New Orleans, and creating a Board of Health for the city. This was not proposed on account of any inefficiency of the Board, but only to divest it of a dual character; and, if carried into effect, the change might have proved advantageous to each board. The State Board, however, vigorously and successfully resisted the proposed innovation.

On account of the failure of the United States Government to locate sanitary inspectors in Central America, where the existence of yellow fever is reported, the State Board will send one, and possibly two, experts to traverse that country from Bocas del Torro to Belize, including all places that ship fruit to this city. The fruit steamers are not allowed to carry any passengers unless they are willing to undergo detention at quarantine for the full length of time.

Recently a young lady was fatally poisoned by drinking some red sherbet, purchased from an itinerant confectioner, her companions who had drank some of the same delicacy also being made very sick. An examination of the viscera demonstrated the presence of about a grain of arsenic; and on analyzing the solution of aniline-red used to color the sherbet, one-fifth of a grain of arsenic was found in each ounce.[1] The chemist accounted for the presence of so large a quantity of arsenic in the viscera by the fact, that an acid fruit-juice in contact with the iron or copper of the freezer would dissolve a small quantity of the metal. When the arsenical coloring solution was added, an arsenite of the dissolved metal would be formed and fall to the bottom of the freezer Hence but a small portion of the contents of the freezer would contain arsenic. This accounted for the fact that other persons who had drank sherbet from the same freezer were not affected, and that only those who drank the last of the sherbet in the freezer were poisoned.

[1] The aniline itself contained 1.6 per cent. of arsenious oxide.

NEWS ITEMS.

International Medical Congress: Programme of the Section of Surgery. — The meetings of the Section of Surgery will take place in the chief building of the Exhibition close to the Station, "Lehrter Bahnhof." Entering by the main door, the room for the Surgical Section will be immediately to the left of the entrance hall.

The meetings will be held from 8.30 A.M. until 10.30 A.M. on the days when the general meetings of the Congress take place; from 9 A.M. until 12 P.M. on days when no general meetings take place.

Scientific reports will be made on each day of meeting, first by those surgeons who have accepted the request of the Committee on Organization to report on a certain subject. Only the names of these speakers will be put down in the programme.

The remaining time will be taken up with reports, communications, and demonstrations from other members.

As the opening of the Congress at the general meeting on August 4th may last until 2 P.M., the Surgical Section has agreed to assemble for their first meeting on Tuesday, August 5th.

First meeting, Tuesday, August 5th, from 9 A.M. until 12 P.M. The President of the Committee on Organization, Mr. Bardeleben, will welcome the members; after this he will request the election of the Secretaries and five Presidents for the five different meetings. The election being finished, Mr. Bardeleben will give the chair to the President elected for the first meeting.

Scientific reports will be made by: 1. Mr. Ollier (Lyon, France), On the Surgical Osteogenesis. 2. Mr. König (Göttingen, Germany), On Hydrops Tuberculosus of the Cavum Peritonei and its Treatment.

Second meeting, Wednesday, August 6th. 1. Mr. Jonathan Hutchinson (London, Great Britain): On the Surgical Treatment of Intussusception. 2. Mr. Billroth (Vienna, Austria): On his Experience in Resection of the Stomach and Intestines.

Third meeting, Thursday, August 7th. 1. Mr. Bottini (Pavia, Italy): On the Treatment of Enlarged Prostate. 2. Mr. Iversen (Copenhagen, Denmark): On Modern Operations for Cancerous Diseases of the Rectum.

Fourth meeting, Friday, August 8th. 1. Dr. Senn (Milwaukee, U. S. A.): On the Diagnosis and Treatment of Gunshot Wounds of the Stomach and Intestines. Illustrated by experiments. 2. Mr. Lewschin (Kasan, Russia): On Vesical Calculus in Russia.

Fifth meeting, Saturday, August 9th. 1. Mr. Rubio (Madrid, Spain): New Method of Decapitation of the Femoral Head. 2. Remaining undelivered reports.

Drs. Bernays, Biondi, Harrison, Keen, Morris, Marck, Newmann, Robson, Schede, Storrs, Wagner, Watson, White, Ziegel, and others, have announced up to the present, reports, presentations of patients, demonstrations of specimens, remarks, etc.

A list will be found in the meeting room for writing down the names and address of the members of the Section.

Any announcements of reports, etc., should be addressed to the Manager of the Committee on Organization for the Section of Surgery, Professor E. von Bergmann, Berlin, N. W., Alexander-Ufer 1.

On the afternoon of the first day of the Congress, Monday, August 4th, at 3 P.M., Dr. E. von Bergmann will be pleased to show to the members of the Section of Surgery the clinical hospital (Ziegelstrasse 5–9), as well as the methods of operating, and the aseptic treatment of wounds practised in the hospital.

The Alvarenga Prize.—The Alvarenga Prize, of the College of Physicians of Philadelphia, consisting of one year's income of the bequest of the late Señor Alvarenga, of Lisbon, has been awarded to Dr. R. W. Philip, of the Victoria Dispensary for Consumption and Diseases of the Chest, Edinburgh, for his essay on Pulmonary Tuberculosis, which will be published by the college.

Obituary.—Dr. Willis F. Westmoreland, one of the best-known surgeons of Georgia, died in Atlanta, on June 27th. Dr. Westmoreland in 1855 founded the *Atlanta Medical and Surgical Journal*, and continued as one of the editors to the time of his death. He was also Professor of Surgery in the Atlanta Medical College. He was graduated by the Jefferson Medical College in 1890.

Fifth District Branch of the New York State Medical Association.—The eighth special meeting of the Fifth District Branch of the New York State Medical Association was held at Kingston, New York, July 22d. Papers were read by Drs. T. H. Manley, J. G. Porteous, J. D. Sullivan, and others.

McGill University, Montreal.—Dr. G. E. Fenwick has resigned the chair of surgery at the McGill University, owing to impaired health. Dr. T. G. Roddick, one of the editors of the *Montreal Medical Journal*, will be Dr. Fenwick's successor.

A Students' Aid Organization at Paris.—M. Pasteur is the chairman of a committee, formed at the Sorbonne, for encouraging foreign students to enter the University of Paris. The committee proposes to assist strangers immediately upon their arrival in the city for the purposes of study, and to furnish gratuitously a kind of bureau of information and elementary advice.

State Board of Health Precautionary Circulars.—The Pennsylvania State Board of Health has issued a series of circulars entitled, "Precautions against Consumption;" "Precautions against Contagious and Infectious Diseases;" "Precautions against Typhoid Fever;" "Precautions against Scarlet Fever;" and "School Hygiene."

These circulars are written in a manner that makes them instructive both to physician and to the general public, and they should be widely distributed.

They will be mailed to any address upon receipt of a request and a two-cent postage stamp, by Dr. Benjamin Lee, Secretary of the Board, Philadelphia.

Bellevue Hospital.—It is stated that the Commissioners of Charities of New York City have obtained possession of real estate near Bellevue Hospital which will increase the depth of the hospital 150 feet, an extension that has been greatly needed for some years.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 15 TO JULY 21, 1890.

By direction of the Secretary of War, leave of absence for three months, to take effect September 15, 1890, or as soon thereafter as his services can be spared, is granted to WILLIAM H. ARTHUR, *Captain and Assistant Surgeon.*—Par. 1, *S. O. 160, A. G. O., Washington, D. C.*, July 11, 1890.

By direction of the Secretary of War, the leave of absence on surgeon's certificate of disability granted LOUIS M. MANS, *Captain and Assistant Surgeon*, in S. O. 4, January 6, 1890, from this office, is extended six months on account of sickness.—Par. 16, *S. O. 160, A. G. O., Washington, D. C.*, July 11, 1890.

By direction of the Secretary of War, leave of absence for four months, on surgeon's certificate of disability, with permission to leave the Division of Missouri, is granted WILLIAM H. CORBUSIER, *Captain and Assistant Surgeon.*—Par. 4, *S. O. 162, Washington*, July 14, 1890.

PAGE, CHARLES, *Colonel and Assistant Surgeon-General*, Medical Director of the Department, is granted leave of absence for one month, to take effect the 30th instant.—Par. 3, *S. O. 91, Department of Missouri, St. Louis, Mo.*, July 14, 1890.

By direction of the Secretary of War, leave of absence for two months is granted JOHN F. PHILLIPS, *Captain and Assistant Surgeon.*—Par. 4, *S. O. 164, Headquarters of the Army, A. G. O., Washington*, July 16, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING JULY 19, 1890.

AUZALL, E. W., *Assistant Surgeon.*—Detached from U. S. S. "Galena," and to await orders.

ECKSTINE, A. C., *Surgeon.*—Granted leave of absence for month of August.

PENROSE, T. M., *Medical Inspector.*—Granted leave of absence for two weeks.

CABELL, A. G., *Passed Assistant Surgeon.*—Granted leave of absence for the month of August.

ASHBRIDGE, RICHARD, *Passed Assistant Surgeon.*—Granted one month's sick leave.

HEYL, T. C., *Surgeon.*—Granted leave of absence for the month of August.

COOKE, GEORGE H., *Medical Inspector.*—Detached from Navy Yard, League Island, and ordered to the "Pensacola."

WHITE, C. H., *Medical Inspector.*—Detached from the "Pensacola," to proceed home and wait orders.

HOEHLING, A. A., *Medical Inspector.*—Detached from Naval Hospital, Washington, and ordered to League Island Navy Yard.

WELLS, H. M., *Medical Inspector.*—Detached from Museum of Hygiene and ordered to Naval Hospital, Washington, D. C.

WHITFIELD, JAMES M., *Assistant Surgeon.*—Ordered to the U. S. S. "Ajax" and other monitors.

WOOLVERTON, THERRON, *Medical Inspector.*—Ordered to the U. S. S. "Philadelphia."

LEVERING, P. A., *Passed Assistant Surgeon.*—Detached from the U. S. R. S. "Wabash," and ordered to the U. S. S. "Philadelphia."

BAILEY, T. B., *Assistant Surgeon.*—Detached from the U. S. R. S. "St. Louis," and ordered to the U. S. S. "Philadelphia."

WHITE, S. S. *Passed Assistant Surgeon.*—Ordered to the Marine Rendezvous, San Francisco, Cal.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

DIATHESES AS APPLIED TO SURGERY. GANGRENE IN ITS VARIOUS FORMS. REMOVAL OF A GANGRENOUS CANCER.

A Clinical Lecture, delivered at the Philadelphia Hospital.

BY ERNEST LAPLACE, M.D.

PROFESSOR OF PATHOLOGY AND CLINICAL SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE; VISITING SURGEON TO THE PHILADELPHIA HOSPITAL, ETC.

[Reported by W. A. NEWMAN DORLAND, M.D.]

GENTLEMEN: There is at present a dearth of surgical material in our wards, and in view of that fact I desire to speak, during a portion of my hour, upon the general question of diatheses, especially as applied to surgery. There are two words, "*diathesis*" and "*cachexia*," which are frequently employed by all of us, but which to many are very indefinite in their meaning. Especially is this so with students, and often it is long before they acquire an accurate knowledge as to what is understood by these terms. It is well here, as elsewhere, to possess always fixed ideas as to the meaning of technical terms. The word "diathesis" comes from two Greek words, and means "I dispose" or "predispose." The word "cachexia" also comes from the Greek, and means a "bad existence." Therefore, a diathesis is an inherited predisposition to a certain disease, while a cachexia is an acquired condition in which the body has lost its former normal state from having passed through some pathological condition. For instance, we speak of the malarial cachexia as existing in an individual who, though not suffering from malaria at the time, still has the appearance of having had that disease; while we know that a child the offspring of tuberculous parents is born with the so-called tubercular diathesis. From time immemorial it was evident that parentage had something to do with the condition of health and of disease as occurring in the offspring. Especially has this been marked among the lower animals, and if it be true here, how much more forcible must it be in man who is the paragon of animals! Also it is true that civilization is to man what domestication is to the inferior animals.

With this introduction let me say a few words regarding the various diatheses with which we are acquainted. The one we most frequently speak of is the tubercular diathesis, a term which is indiscriminately used with tuberculosis, scrofula, and scrofulosis. Let me establish here what we mean by the tubercular diathesis. A child born of parents who have had or who have inherited tuberculosis, need not have any evidence of the disease itself in order to possess the tubercular diathesis. The appearance of children with this diathesis is characteristic. Generally they are bright children, fair, with blue eyes and transparent skin, the marvel of the neighborhood, never very strong, and irritable in disposition. They are only waiting for the occasion to develop tuberculosis. Now suppose that two children receive a fall, the one a healthy child, and the other one of these bright children. The healthy child will suffer a contusion of his knee which will be well in two or three days. Not so the other child. The contusion is followed by a swelling in the knee-joint, and the child develops a "white swelling," or tuberculous disease of the joint. Both of these children had been breathing the germs of tuberculosis since birth, and the germs had not developed because there was not a suitable condition of the system. Now the one child falls, and from this slight cause the development takes place, and the disease manifests itself, whereas, in the healthy child the germ still resists development.

Now, what do we understand by scrofulosis? A child with scrofulosis is one with tuberculosis of its lymphatic glands. From the moment the symptoms of scrofula appear, the child is tuberculous, for the germs have begun to develop within the glandular system. There are no reliable cases on record to warrant the belief that a child is ever born with fully developed tuberculosis in its system. It must, therefore, be born with the tubercular diathesis, to develop sooner or later tuberculosis in one of its forms; either as scrofulosis, or tuberculosis of the lymphatic glands; as "white swelling," or tuberculosis of the knee-joint; as tubercular meningitis; as cold abscesses in various parts of the body; or finally, later in life as that most fatal development of tuberculosis, tuberculosis of the lungs. There are many among us who, if they lived according to the laws of hygiene, would never develop tuberculosis; but the most of us, if placed under improper hygienic conditions, would contract the disease from the development of the germs which we now breathe with impunity. It is possible, thus for a person who has not the tubercular diathesis to develop the disease if the proper soil is acquired, and this soil is called the cachexia.

Leaving, now, the question of tuberculosis, let us take up that of syphilis. Syphilis is also a condition in which a diathesis exists, but unlike tuberculosis the child may be born with the affection fully developed. Cancer is another affection exactly in the same condition, so far as development is concerned, as syphilis. There are cases on record of children who have been born with fully developed cancers of the mesentery. These cases, though extremely rare, are sufficient to prove the assertion. The malarial poison, the poison of syphilis, tuberculosis, etc., all starting as cachexiæ may manifest themselves as diatheses in our children. Suppose now that a person who is perfectly healthy acquires tuberculosis. He will very probably give the diathesis to his offspring.

What, then, is the difference between a person who has the tubercular diathesis and one who has not? It is purely a chemical difference, possibly modified by tem-

perature. Since we know to-day that the tuberculous condition is due to a peculiar seed, the tubercle bacillus, falling upon a suitable soil, just as a certain seed falling into the ground will develop a particular plant, or as one soil is suitable for the development of wheat, and another for the development of corn, so, I say, in these cases the only difference is one of a chemical nature; the soil not being suitable to the development of the germ in the one, and being suitable in the other. There is a true chemical difference in the albuminoids of the two persons, a difference at present inappreciable to chemists, but which, judging from the present state of investigations, will shortly be discovered.

Gentlemen, this is no hypothesis, but we are speaking of something which can be demonstrated as clearly as that two and two make four. If we take a proper preparation of agar-agar and add to it four per cent. of glycerin, the tubercle bacillus will grow and develop; but if we add six or eight per cent. of glycerin, the tubercle bacillus will not grow. The agar-agar preparation with the four per cent. of glycerin is the tuberculous child, and the germ grows; the agar-agar solution with the eight per cent. of glycerin is us, on whom, though the germs fall, they will not grow. Therefore, since these things can be demonstrated in any bacteriological laboratory, cannot any logical mind draw the inference that the same thing will occur in the individual?

One more fact to illustrate this idea. Diseases are different because the germs which produce them are different, though the soil be the same. Eight years ago, in the Academy of Sciences of Paris, Pasteur had just discovered a method of inoculating for splenic fever in animals. It was known that splenic fever would not attack fowls, though it did attack both beasts and man. On the other hand, Pasteur had noticed that the germ of the disease at the temperature of the human body was deadly, while if the temperature was raised a few degrees higher the germ became inert. Then the thought occurred to him to investigate the temperature of fowls, and he found that it was 101°, the same temperature at which the germ became innocent. At once he reasoned that this was why the germ would not grow. He took the fowl and put it into cold water, and reducing the temperature in this way, he introduced the germ, which now grew and killed the fowl. What could be more conclusive than the effect of temperature in producing disease? Thus two men get a wetting; the one develops a pneumonia, because his temperature has become reduced, while the other escapes, his temperature remaining normal at the time of exposure.

Let us now see what is to be done from a remedial standpoint. What should be done to preserve ourselves against these conditions? The first one to turn our minds into the right direction was Jenner, the discoverer of vaccination, or the introduction into the body of a certain amount of a living chemical substance which when developed in the body causes the soil to become barren. This being the case with smallpox, what a great field lies before us, as many affections are due to microorganisms capable of development, but which may be be prevented from developing by altering the condition of the soil! What great opportunities are afforded us for studying these germs and their processes of development! The other conditions which are acquired from vices or alcoholic excesses may easily be removed, and the time may yet come when Addison's allegory, the Vision of Mirza, will prove indeed only a dream. Instead of the seventy broken columns, with the path beset with snares and pitfalls, there will be one hundred complete columns, and a perfect highway along which man may travel happy and healthy to the Elysian fields beyond.

The next patient shows a condition of gangrene—a very important subject. Gangrene is always due to some interference in the circulation, either arterial or venous, or often both. If arterial, we have the dry form of gangrene; if venous, the moist form; if due to interference with both arteries and veins, we have capillary gangrene, such as occurs in old age, or as a result of a severe bruise, or following that condition of the system produced by certain remedies, as ergot. Here is this old woman suffering from senile gangrene. Her circulation is too weak to afford proper nourishment to the toes. The patient came into the hospital three days ago in a pretty fair condition. Very often this disease is self-limiting, and so we waited; but there does not seem to be any tendency to self-limitation. The proper treatment in these cases is amputation, not close to the gangrenous area, but far from it. The amputation here should be just below the knee. The patient has developed septicæmia, and is now suffering from septic pneumonia, and operation would probably not be followed by success. Yet if she would give consent—which she positively refuses to do—I would operate. Gangrene always results from cessation of the circulation, and is a process of putrefaction and fermentation. The odor is due chiefly to sulphuretted hydrogen. There is also developed carbonic acid, which we can see coming in bubbles from under the skin.

Here is another patient who presented on entrance a condition of gangrene. She suffered a severe fall and, as a result, experienced great contusion of the parts around the anus, sufficient to impair the vitality and permeable condition of the bloodvessels. There is sloughing of the parts, which is nothing more nor less than gangrene. When this slough comes off we call it a sphacelus. The wound to-day looks very healthy.

The next case is the one I brought before you when I was speaking of metastasis in cancer. To-day I bring him here to show you another case of gangrene, and to operate upon him. The man is young, and the metastasis in his groin is rapidly progressing; therefore I shall try to remove most of the disease, and, by the application of proper remedies, endeavor to destroy the disease-germ as far as possible. Around the ulceration you will notice these large, dark spots, which are gangrenous in nature. The poison developing there is directly interfering with the circulation. Just as we see the chemical poison of a snake-bite, or the poison of ergot or of carbonic acid producing gangrene, so here we see the poison of disease causing his gangrene. Therefore, remember that microörganisms may also excite gangrene when growing in certain tissues, as may be seen in the case of a carbuncle, which is due to the staphylococcus pyogenes aureus.

While waiting for the case to be etherized, I will say that the cure of cancer should not be considered hopeless. At the recent Congress of Surgeons in Berlin

there were reported six undoubted cures of epithelioma and sarcoma by the following treatment. About twenty years ago a French surgeon, still living, had a case of cancer of the breast which was too far advanced for operation. As the surgeon was not very cleanly, not being acquainted with our methods of antisepsis, the patient developed erysipelas, and after nearly dying, recovered. About a month later she had a second attack of erysipelas, after which the growth took on a benign appearance and progressed to recovery. Since then two surgeons have been inoculating cancerous patients with the germs of erysipelas, and now report the cure of six cases.

The patient now being ready I shall proceed to cut away with scissors as much of this gangrenous tissue as possible. The femoral artery is in this region, and is probably not far from the inroads of the disease. I shall therefore be very careful in the use of the curette.

CIRCUMCISION.

By E. R. PALMER, M.D.,
of Louisville, Ky

In offering for consideration the subject of circumcision I am certainly not actuated by the idea of novelty. The veil of mystery of old that has never been lifted, that still enshrouds the reasons that impelled Abraham to institute this operation among the chosen people; the persistence with which the rite has been performed upon the males of that people in epochs of prosperity and in ages of adversity should have given us a definite literature of the subject from a surgical standpoint. That this is not the fact, and that crudities still cluster around the operation, whether done as a religious rite or as a surgical necessity, are among the reasons that have suggested this paper.

Before entering into a consideration of the purely scientific or surgical aspect of my subject, its relations to the laws of heredity and evolution may well be considered. The development of new species by the selection and cultivation of "sports" in the botanical kingdom is a common occurrence. In the animal world the once famous Ancon sheep of New England were bred from a bench-legged "accident of birth." The tailless and the hairless families of dogs still further illustrate the power of heredity by selection. Among men the transmission of supernumerary toes or fingers through generations, a transmission of tendency to redundancy, is probably the best of the few instances I can choose for illustration, unless the growing tendency to early baldness, which is clearly hereditary, may be pointed to as presaging a coming family of hairless humanity.

What of circumcision? Has this most venerable rite had any effect on the length of the normal Hebrew prepuce? In reply I will quote from two recent editorials in the *New York Medical Journal*.

"Are Mutilations Inherited? *The Lancet*, in a recent issue, discusses this subject and refers to some recent studies by Professor Weismann on the subject. The distinguished professor cut off the tails of nine hundred and one white mice of successive generations, but in no case was a white mouse born without a full-sized tail. It has always been something of a puzzle that Jews should, after thousands of years of circumcision, still bear infants with long prepuces. Darwin refers to the fact, as noted by Gordon, that different races of men have from time immemorial knocked out their upper incisors, cut off joints of their fingers, made holes of immense size through the lobes of their ears or through their nostrils, tattooed themselves, made deep gashes in various parts of their bodies, and yet there is no reason to suppose that these mutilations have ever been inherited.

"It must be conceded that, in the higher mammals, at least, mutilations are rarely, if ever, transmitted."

"Dr. Levy, a dentist of Stettin, has written to the editor of the *Archiv für pathologische Anatomie und Physiologie und für klinische Medicin* an account of some occurrences in his own family that have a bearing, he thinks, on a question raised by Professor Weismann at the sixty-first 'Versammlung Deutscher Naturforscher und Aerzte'—that of the hereditary transmission of acquired peculiarities, such as the lack of a foreskin in Jews. He states that, like his father before him, he was born without a foreskin—as he expresses it, '*regelrecht beschnitten*'—furthermore, that this was the case with his four brothers also, who died in childhood. An occasional natural *apelle* is to be met with among Gentiles, but this, of course, raises no question of heredity; such a group of them as Dr. Levy's communication mentions is a different matter, however, although not a very convincing evidence of evolution."

In my personal experience I can report a single case, that of a young man of Jewish lineage who came to me with a stricture. On exposing the penis an excessively redundant prepuce presented. In answer to my query, the young man said that when he was born his father lived in the country, in a sparsely settled region, where no one could be found to perform the rite. The cases in the Levy family raise another question whose answer I think readily explains the peculiarities. Do all baby boys left uncircumcised grow to man's estate with redundant foreskins? In my opinion the answer is. Not more than two-thirds. How is this to be explained? Boys are born with adherent prepuces as puppies are with closed eyes—a normal evolution of the parts should give a loose, freely retractable prepuce, covering about half the glans during rest. This is the typical evolution of these parts. Sometimes at one extreme the organ in the uncircumcised, except for the absence of scar marks cannot be told from one that has been operated upon, a condition that has by some surgeons been atributed to excessive masturbation in early youth. In others a prepuce closely adherent to the glans, or congenital stenosis of the preputial orifice may be observed. Probably each of us has seen adults presenting the latter condition where a ballooning of

the preputial sac occurred on any attempt at free urination.

Should boy babies be circumcised? In most cases they should. But as done by the *mohel* the operation is needlessly painful, occasionally fruitful of permanent harm, and sometimes dangerous to life itself. In examining young men of Jewish families I have a number of times noted the removal of the tip of the glans itself, leaving behind not only a troublesome traumatic stenosis, but what is worse, possible barrenness, whilst cicatricial bands and disfiguring scars innumerable have been observed again and again. How should the operation be done?

In very early life it is an exceedingly simple operation. All that is needed is to assist nature in the normal evolution of the parts. The proper operation lies between two extremes. It is not necessary to remove tissue, nor will ordinary divulsion with forceps suffice. The operation of splitting the upper surface well back on a grooved director with a pair of scissors is all that is necessary, no stitching being called for, and only a simple antiseptic dressing is required. I grant with others that this is on the adult an exceedingly unsurgical procedure as a rule, leaving as it does useless and unsightly ears on either side. Not so, however, with the babe. In the adult the evolution of the parts is complete; in the babe the operation acts like the woodman's tree-belting. Beyond the base of the slit evolution ceases and a scarless *apelle* is the result. I first saw this operation done eighteen years ago, and I had occasion the other day to examine the babe, now grown. The result was all that could be desired. I have done the operation many times in later years, and am so far pleased with the outcome. As I said before, this method is usually an unsurgical procedure in the adult. Occasionally one presents with a scant but very tightly fitting cover, and here splitting may be indicated. I believe that were the ritualist, the *mohel*, to split freely only, and then thoroughly separate the adherent surfaces, giving proper directions to the nurse for keeping them so, he would accomplish safely, quickly, and almost painlessly all that reason and science at least could ask. In after years, I question if the subject would be distinguishable from one operated on by the old method, except by the superior beauty of the result.

It would consume too much time to go into a detailed account of the various neuroses of childhood that are attributable to a long foreskin. Their recognition makes it imperative that every doctor should examine all boy babies in his charge, whether sick or well, and see that the condition if existing be removed.

When should circumcision be performed in the adult? In what class of cases? First, in all men who, otherwise sound, possess a long, non-adherent prepuce that is so narrow at its orifice, or so glove-fitting in its nature as to prevent easy retraction while in a state of complete erection. Second, in cases of redundant prepuce, where only extreme cleanliness and care can prevent frequently recurring excoriations or ordinary balanitis; and, finally, in the group of cases where, notwithstanding that the prepuce is freely movable, full erection fails to uncover the glans.

The following conditions call for the operation in disease: First, preparatory to urethrotomy in gleet with stricture, where a long, close, and troublesome foreskin constantly projects itself into the operator's way. Second, in cases with chronic herpetic and balanitic tendencies. Third, *in syphilis*, where (*a*) the chancre may by such an operative procedure be removed, and where (*b*) syphilitic hyperplasia of a general and extensive type produces phimosis or furnishes in useless tissue a nidus for the further evolution of poison, it being a matter of frequent observation that extreme syphilitic infiltration is no obstacle to ready union after operation.

Finally, shall we circumcise in phimosis complicated with chancroids? I confess that I have in the past been often at sea in such conditions. Influenced by the teachings of authorities I have again and again in spite of extreme care had chancroids escape control and do much harm under a tight phimosis. Now, in many cases, I have by operating early not only avoided this accident but cut short the disease.

When shall we operate in these cases? The answer is found in the condition of the groin. If the lymphatic glands are not involved the operation may be safely performed. If hot, rapidly advancing adenitis exists, to operate would be to assume a grave responsibility, yet even in such cases with our present increased knowledge of the laws and control of sepsis I would frequently fear the knife less than the disease itself, concealed deep beneath the fixed and swollen foreskin. In the last few months I have operated in such cases four times, using the extremest care in the matter of quick cauterization and antiseptic after-treatment, and in such cases the result has been all that could be desired. In the last case, a young Irishman of not over-cleanly habits or occupation, the excision showed a large, gray suppurating sore that had just destroyed the frænum. Cauterization with pure carbolic acid was done, the wound was washed with bichloride solution and dressed with iodoform. Two days later there suddenly appeared in the left groin a huge bubo—a so-called sympathetic bubo—which almost as suddenly disappeared under the pressure of a spica bandage. The healthy tissue of the cut united nicely, and though the sore was some weeks

in healing, no new infection followed. This is typical of my other cases.

There is a group of cases that comes under this class about which there should not be a moment's hesitation. Every city practitioner meets with them. They present on the free edge of a long prepuce grayish ulcers or often, at first, fissures only, sometimes single, sometimes multiple, but with a marked tendency to extend and to resist treatment. When the foreskin is in place, they are usually concealed in a fold. To expose them it is necessary to retract the part partially, which tears them open and tends to increase their extent. I formerly wrestled with such cases for a month or two, but now by immediate circumcision the cases are not only at once cured but the disease is forever afterward prevented from returning.

I shall not weary the reader with general details of operative procedure, but will emphasize only a few of the important points.

Immediately before operating in cases of gleet, wash out the urethra, by means of a Jacque's catheter, with a hot 1-to-15,000 bichloride solution. In cases of balanitis or excoriation dress the parts twice daily for several days before the operation, with cotton wet in saturated solution of boric acid. In case of chancroids, touch every visible sore with pure carbolic acid just before operating, and in *all cases* cleanse the parts and surroundings very thoroughly with hot 1-to-2000 bichloride solution, being especially careful to purify thoroughly the balanopreputial fold. Chloroform or ether need never be used; 4-per-cent. cocaine solution injected into and beneath the skin with a hypodermic syringe and incarcerated by the Corning method is sufficient. In applying your rubber for this purpose follow the Esmarch method. It will give a bloodless operation.

A familiar problem has been how to cut both skin and mucous membrane at the same time. It is an idle and fallacious problem. In some cases, for instance of chronic balanitis, very little mucous membrane and more skin is desirable. By trimming the mucous membrane after removing the skin one is enabled, looking always to the preservation of the frænum, to prevent bridling at that point during future erections. Like a tailor fitting the sleeve to a garment the surgeon should cut diagonally, beginning close to the glans on the dorsum and shading out to a lengthy frænum below. Speaking of cutting both layers at once, it is of especial importance to recognize that not two but three coats must be cut if a neat operation with speedy union is the aim. After trimming the mucous layer, and just before introducing the stitches, the connective tissue in the bottom of the wound should be seized with a pair of small dressing forceps, drawn outward and then with scissors be carefully clipped away around the entire circumference of the floor. Where this is neglected the now useless tissue will push outward between the stitches and, later, leave a ring of induration that is a long time in finally disappearing. In the matter of stitching, having tried both the interrupted and continuous suture, I have found that after removal of connective tissue from four to six interrupted silk stitches are all that is needed. It is the rule with some excellent surgeons always to destroy the frænum. Not only should this not be done, but, so far as possible, where it has by previous accident been ruptured, it should be restored.

What is the frænum? What are its functions? In the mechanism of erection while the corpus spongiosum enlarges at its two extremities, its erection is chiefly characterized by *elongation*, carrying with it the cavernous bodies that at the same time expand laterally to give increased circumference to the organ. When the penis is flaccid the scrotum is in most cases pronouncedly pendulous. In erection the testicles hug closely to the region of the bulb, for the frænum has done its duty and carried upward with the ascending glans the scrotal raiment of the now fully erect organ. To destroy wholly the frænum entails inevitably a diminution in the size of the organ during erection. Nor is this the only office of the frænum. In the introduction of the cocaine during the cutting, trimming, and sewing, one point is always painful—the frænum. Why? Because it is the centre of penile sensation. Because, more than the entire surface of the glans does it possess that exquisite sensitiveness with which the bulbs of Krause endow these parts. During erection not only does it draw upward the lax scrotum as a covering for the organ, but its two edges acutely sensitive and now thoroughly tense, like vocal cords, voice the passion that overpowers. My first stitch looks always to the preservation or restoration of this part.

In former years, circumcision in the adult meant a week, perhaps more, of confinement in bed and room. Under modern methods not an hour need be lost from business. This is in part due to the substitution of local for general anæsthesia, but mainly to the antiseptic precautions used, including dressings, of which I shall in conclusion say a few words.

I spoke a while ago of the thorough use of a 1-to-2000 solution of bichloride in the preparatory cleansing. From a brilliant young Kentuckian, Dr. John Young Brown, I have learned the value of absolute dryness during the operation and in the after-dressing. Formerly I encountered frequent and annoying tumefaction of the adjacent parts, which I thought was due to the cocaine. At Dr. Brown's suggestion I operated and dressed dry, and have

never encountered that trouble since. Even in case of hæmorrhage, which is, however, rarely a factor in the operation, the cotton should be absolutely dry. Like others I am not opposed to blood in dressings if it is *clean* blood. A little oozing all around the line is not objectionable. After stitching, a piece of dry, aseptic gauze, four inches long and an inch and a half wide, covered with iodoform and boric acid, and spread on a clean towel, is laid under the frænum, brought up around the cut, right and left, to the dorsum and trimmed with scissors. Over this a strip of absorbent cotton, three-quarters of an inch wide, is applied. Next, a Maltese cross of dry gauze, with a central hole for the meatus, is applied, and then a similar cross of rubber tissue, and the whole bandaged snugly in place. A waist belt, a jock strap, and a bunch of cotton, to cover the glans, well dusted with boric acid, complete a dressing that permits the subject to go to work at once at any ordinary vocation. By directing the patient to retract the dressing on urinating and to absorb the final drops with a soft cloth this original dressing may be left on five days. When the stitches are removed the parts should be dusted with boric acid, a loose pledget of cotton wrapped around them, and the patient discharged.

Occasionally, owing to oozing of blood, it may be found necessary to apply the dressing too tightly for permanency. In such cases an extra one-inch roller may be applied over the permanent dressing, to be removed some hours later without disturbing the dressing proper.

THE CAUSES AND TREATMENT OF PNEUMONIA.[1]

By J. M. G. CARTER, M.D., Sc.D., Ph D.,
of Waukegan, Ill.
Fellow of the American Academy of Medicine; Member of the American Medical Association, etc.,

Pneumonia is one of the diseases best known to the medical profession, but that a disease is well known and easily diagnosed does not necessarily imply that it is thoroughly understood. When a disease is said to be thoroughly understood, it is meant that its etiology, its processes, or pathological modifications, its sequelæ, and its proper treatment are known and accepted as settled by the profession. It was formerly supposed that idiopathic pneumonia was due to some atmospheric influence which, by checking the peripheral circulation, turned the blood-current with greater force to the lungs, the result of which was congestion and inflammation. This is still considered the pathological process, but the question of etiology has given rise to some discussion, and, in many minds, to doubt.

[1] Read before the Illinois State Medical Society, May, 1890.

The germ theory, which is accepted as the explanation of many diseases, has been advanced to explain the origin of pneumonia. Since the discovery of the peculiar form of bacteria in the lungs of persons dead from pneumonia, a discovery made by Friedländer and Frobenius, much thought has been given to the bacterial theory of the disease. Six different varieties of bacteria have been mentioned by Bremner as causing this disease, and others have been mentioned by later writers. The diplococcus of Fränkel has lately been shown to be present in most cases of pneumonia, especially croupous pneumonia. Wolff found it in ninety-four per cent. of the cases examined by him, there being but a single negative result in seventy successive cases. Baumgarten thinks it is safe to assume a single cause for pneumonia. In Wolff's cases verification was established by cultures in more than half the cases.

The first investigations were made after death, but later authors have examined sputa and exudations from the lungs. Monti examined the exuded fluid in twenty cases, with but one negative result. Sometimes the Fränkel diplococcus was found in company with other bacteria. In these cases of Monti, Friedländer's micrococcus was not seen. Inoculation of fifty-nine rabbits, while universally successful, produced typical pneumonia only when the sputum was introduced into the trachea. Inoculation under the skin produces septicæmia; into the pleura, pleurisy; into the pericardium, pericarditis. Inoculation into the dura mater of a dog produced meningitis and lobar pneumonia. Fränkel, Foa, Whittaker, and others have shown that the cause of pneumonia is not confined to the lungs, but invades other organs and tissues. Weichselbaum, Netter, Mircoli, and others, have found the diplococcus, after pneumonia, in the ventricles of the brain, connective tissue of the mediastinum, and in that about the clavicle, in the cavities about the nose, and in the drum-cavity and labyrinth of the ear. It has been cultivated from the serum of the pericardium, before there were any visible signs of inflammation. It has been found, likewise, in inflammations of the spinal cord.

Emmerich found great numbers of bacteria of the varieties here referred to under the floor of a hospital ward where many cases of pneumonia had been treated.

Writing in regard to pneumonia proper, Weichselbaum sums up his conclusions as follows:

1. "The bacteria found in different forms of pulmonary inflammation are regarded as the cause of them. This conclusion is completely justified on the following grounds: Definite, well-characterized species of bacteria not only occur constantly in acute pulmonary inflammations, but can be demonstrated in greatest abundance and activity in the earlier stages of inflammations. They have been isolated, cultivated, and, when introduced into certain animals, have produced processes which,

taking them *in toto*, correspond to inflammation of the lung in man.

2. "The pulmonic virus is no unity, inasmuch as acute pulmonary inflammations, even croupous pneumonia proper, can be produced by different kinds of bacteria. In this the pneumonias recall acute inflammation of the connective tissue, in which several species of organisms occur.

3. "The separation of pneumonias into lobular and lobar, croupous and non-croupous, has an anatomical, but no etiological significance. Moreover, the so-called secondary pneumonias, etiologically considered, are not secondary.

4. "The diplococcus pneumonia is to be regarded as the most frequent exciter of inflammation of the lungs. Friedländer's bacillus but rarely causes croupous pneumonia. 'Catching cold' has only a possible predisposing effect."

This summary is, perhaps, a clear representation of the opinion held by the majority, of bacteriologists at least, at the present time. The opinions of general practitioners are universally more conservative than those of specialists, and many able physicians still hesitate to accept the theories and radical views of some bacteriologists. It is well known that there is much study devoted to this subject at the present time, and many investigations have been made during the past year, but, perhaps, nothing can be added to the stock of knowledge or opinions detailed above. Dr. F. S. Billings, of Chicago, informs me that nothing new has been discovered; and as his personal views correspond with those of most other bacteriologists, I will quote his own words: "Personally, I do not think either the Weichselbaum, Fränkel, or Friedländer organism has any specific relation to pneumonia in man." He gives, as a reason or basis for this opinion, "That they are present in the mouths of healthy individuals, and do not cause pneumonia, and have also been found attached to the bronchial mucosa of persons killed by accident or dying with intact lungs;" but he further states that, "When active and prolonged congestion with serous bronchial effusion is present, then they may cause pneumonia."

When an epidemic of a disease caused by bacteria occurs it is said that the air is filled with them. Professor Nussbaum has stated that during an epidemic of cholera the air is filled with cholera bacilli, and yet only one per cent. of the population is affected by the disease. Hence ninety-nine people in every hundred, though eating, drinking, and breathing cholera bacilli escape the disease. Such may well be believed to be the case with the bacillus of pneumonia, though it must be less powerful in its activities than that of cholera.

It is well known that pneumonia is more prevalent in some seasons than others, and that it occurs most frequently under certain atmospheric conditions. Perhaps most cases occur during the winter and spring months. The humidity of the atmosphere and the presence of ozone also seem to exert a causative influence. On October 12, 1889, at Waukegan, Ill., the wind was in the southwest; it suddenly changed to the northeast, the temperature fell from 70° to 50°, and the ozone in the atmosphere was increased. Several cases of catarrhal pneumonia occurred, the apparent cause being the change in the condition of the atmosphere. I noticed, however, that during the same period, many cases of pneumonia were reported in other localities. On February 15, 1890, the wind was in the southwest; the temperature rose from 30° to 65°; ozone was not marked; the atmosphere was humid, and there were several cases of pneumonia. From April 1st to 5th the wind was mostly from the east and southeast, it was rainy and warmer, the temperature varying from 40° to 65°. New cases of pneumonia developed. Such observations are prone to make one believe that atmospheric changes are causative of the disease. Jaccoud, while not denying the etiological influence of bacteria, holds that exposure to cold is also causative, and perhaps generally the exciting cause.

Dr. Baker demonstrated before the Brooklyn Pathological Society that the curve representative of sickness from pneumonia pretty regularly followed the curve of temperature. His studies extended over many years and included nearly fifty thousand cases of pneumonia. He showed, in all his references, "that the sickness curve follows the temperature curve, not only in pneumonia, but also in bronchitis. If pneumonia were due to bacteriological influence, this cause must certainly be influenced by the weather, and more than that, bronchitis would probably be caused by the same germ."

Sevestre considers that certain cases of endemic and epidemic broncho-pneumonia in children during the summer months are due to dietary indiscretion, the inflammation extending to the lungs from the intestines through the lymph-channels.

Tomasi, Golgi, and others believe pneumonia to be sometimes caused by malarial poison, and this view corresponds with that of the physicians in the southern part of Illinois and other malarial districts in the United States, where this form of the disease is called "winter fever."

Dr. Mosny reported to the Academy of Medicine of Paris a case of broncho-pneumonia in a woman who had been nursing a patient with erysipelas. The patient died, and the examination of the exudation in the lungs revealed the fact that the pneumococcus was not present, but that the streptococcus erysipelatis was, showing that the disease in this case was not caused by the bacillus of pneumonia.

At present it must be admitted that the cause of pneumonia is not fully determined, and probably the majority of physicians are not willing to accept

the bacillus theory. It is unproven that the bacillus is not a concomitant rather than the cause of the disease. Future investigations must make the final decision, and probably we shall not wait long before the decision is made.

It has been hoped that the germ theory of disease might lead to specific medication, and it may justly be anticipated, if this theory is true, that absolute cure of many diseases may be promised as soon as germicides are discovered which will kill the germs without injuring the patient. Is this possible? At present we do not know. So far as pneumonia is concerned, the knowledge or lack of knowledge of the presence of pneumococci is of no importance in the treatment of the disease.

In the present state of our knowledge the following indications for the treatment are clear: (1) To equalize the circulation and diminish the determination of blood to the lungs. (2) To reduce the temperature of the body. (3) To sustain the patient's strength. (4) To assist the mucous membranes and organs of secretion and excretion in the performance of their functions. (5) To allay pain.

The first two of these indications are met by the same general treatment. The chief object is to control the high temperature, and this is largely accomplished by reducing the blood-pressure and allaying the excitability of an overworked heart. For these indications I use aconite, gelsemium, or digitalis, according to the grade of the fever and the condition of the lungs, the heart, and the stomach. In high fever, with strong, bounding pulse, I use aconite and add gelsemium if there is irritable stomach with or without headache. Petresco says that digitalis may check pneumonia at the outset. It is of value in asthenic cases and where the heart is weak. Convallaria is sometimes advantageously substituted when digitalis is not well borne.

I have not been favorably impressed with antipyrine nor with antifebrin, and of late have not given them. Dr. Humphreys remarks that antipyrine should not generally be given in catarrhal pneumonia nor in lobar pneumonia when there is œdema of the lungs.

Quinine is usually serviceable, and in malarial cases is essential, not only to reduce temperature, but also as a germicide and antiperiodic. But in some cases it has a bad effect upon the stomach and nervous system. Dr. Jacobi believes that quinine lessens pulmonary congestion and strengthens the heart's action. Alcohol, brandy or whiskey in large doses will help to reduce temperature and equalize the circulation. It has seemed to me that the alcohol secures this result by its action on the vaso-motor system. I have also seen most beneficial results from early blistering with cantharides, which not only alleviates pain but assists in controlling the congestion.

Liebermeister advises bloodletting when there is œdema of the lungs; but I believe this may be avoided by blistering and the use of digitalis. He is also much in favor of the cold bath, given preferably in the evening. There is no doubt that a wise use of the bath—tepid or cold, as circumstances may require—assists in reducing temperature and has a restorative rather than a debilitating effect.

In many sthenic cases tartar emetic seems to be of special value. Bruckner has reported over seventy cases treated with this drug, in which the success was so marked as to make him enthusiastically in favor of the remedy.

An ice-bag to the head and affected portion of the lung, as recommended by Angel Money, may be used with success, and often gives great comfort to the patient; but, like the baths, it must be used systematically. Money says that the ice-bag acts as a tonic to the heart, to the nervous system, to the muscular system, and to the respiratory centres. It thus aids in the third indication, maintaining the patient's strength. It soothes the motor and sensory systems, and in this way produces sleep.

For the difficult breathing likely to occur on the fifth day, with small and rapid pulse, perhaps nothing is better than camphor, benzoic acid, or valerian. Alcohol in large doses is also beneficial. The inhalation of carbonic acid in broncho-pneumonia, as recommended by Dr. Lamallerée, I have not used. The third indication—the maintenance of the patient's strength—is accomplished chiefly by nourishment. With Fräntzel I recommend absolute rest in bed and liquid nourishment. The patient should be well fed from the beginning. For thirst, lemonade, and mineral and vegetable acids are refrigerant and assist the digestive process. I generally use aromatic sulphuric acid, believing that it may have a salutary influence upon the stomach, liver, and pancreas, and that it aids digestion and assimilation of food.

The secretory functions should be carefully observed, and aid should be given to the mucous membrane of the lungs, to the liver, kidneys, pancreas, and alimentary canal. Ipecacuanha is an invaluable remedy as a stimulant to the mucous membranes and to the liver. Aromatic sulphuric acid is a stimulant to the pancreas, and is of especial value in cases with typhoid symptoms. Digitalis and potassium nitrate are excellent renal stimulants. Mercury, in some form and in small doses, as a stimulant to the liver and intestinal canal is very useful. I prefer the mercury and chalk mixture given for a few days, and then followed by muriate of ammonium.

Pain must be controlled, and for this nothing can

take the place of opium. I am in the habit, in uncomplicated cases, of giving the following prescription:

℞.—Sulphate of quinine . . 30 grains.
Dover's powder . . . 40 "
Mercury with chalk . . 20 "
Mix and divide in 10 capsules.

This dose is for an adult and is varied to suit the patient and his diseased condition. I give it at intervals of four hours. This prescription assists in controlling the congestion, acts as a heart tonic, aids the patient in expectorating, assists the liver and intestinal canal in the performance of their functions, alleviates pain, and, if the Dover's powder is made with the nitrate instead of the sulphate of potassium, stimulates the kidneys.

PERFORATIVE APPENDICITIS, WITH REPORT OF A CASE TREATED BY LAPAROTOMY.[1]

By SCHUYLER C. GRAVES, M.D.,
VISITING SURGEON TO ST. MARKS AND THE U. B. A. HOSPITALS, GRAND RAPIDS, MICH.

The search of the followers of de Soto in the land of flowers for the fountain of perpetual youth forcibly illustrates the yearning of human nature for continued health and happiness. The fountain of youth could not, and never can be, found; but with the astonishing progress of the science and art of medicine and surgery within the past quarter of a century the search for health has become far less discouraging and its discovery very much more possible.

Theories may oft-times be interesting, but facts are always the great *desiderata* in the practice of the healing art.

It is needless to say that facts which have a direct bearing upon the life or death of human beings are of the most vital moment to both patient and surgeon. The surgeon cannot learn too much in regard to them, and he should not fail to profit by the experience of other surgeons who are engaged in the same investigations.

The subject of appendicitis has, of late, attracted world-wide attention in the medical profession. Abdominal surgery in general, and intestinal surgery in particular, have made wonderful strides within the last decade, principally, we are proud to say, through the labors of American surgeons, notably those of Senn and of Parkes.

The terms typhlitis, perityphlitis, and paratyphlitis, although sometimes correctly applied to morbid conditions, have long been surgical misnomers, for what has seemed to be an inflammation *of, around* or *behind* the cæcum, has undoubtedly, in the majority of instances, been an inflammation of the appendix vermiformis. This little organ, rudimentary in its capacity for good, seems to be thoroughly developed in its capacity for evil. Often with slight provocation it takes on a destructive inflammatory activity—an inflammation with an ulcerative tendency—which, very frequently and more or less rapidly, leads to perforation with subsequent intraperitoneal complications of the gravest nature. I say frequently, for we know that inflammation of a purely catarrhal type does occur, although, according to Musser, even this mild inflammation may at any time become ulcerative, subsequently perforating.

The substances which act as the immediate cause of the disease will almost always be found fæcal in character, although, as Musser states, foreign bodies, such as "buttons, bristles, worms, shot, pins, and gall-stones," have been observed. To this list might be added the seed of the grape, lemon, and orange, as well as that of other small-seeded fruit. In regard to the finding of these causative bodies, either before or after death, Greig Smith[1] says that "of 125 cases collected by Dr. Fenwick, in 55 a foreign body was found."

An obstruction of whatsoever nature having occluded the mouth of the appendix, irritation is set up. This is followed by increased secretion on the part of the mucous glands and by the constantly accumulating products of the inflammation which soon supervenes. Unfortunately ulceration is initiated, perforation takes place, and the distended organ gives up its burden of purulent fluid. While these destructive processes, however, are going on in the appendix, nature is busy with constructive processes with the evident aim of limiting the mischief and preventing infection of the general peritoneal cavity. Protective inflammation glues together the intestines in the region of the disease-focus and builds a wall of lymph to oppose and confine the septic matters soon to escape from the appendix. If now adhesive inflammation permits the discharge of the pent-up fluids through a neighboring hollow viscus, or if this protective process be carried to such an extent as to allow the "pointing" of the abscess externally we have a fortunate, natural termination of the trouble; but, unfortunately, we have too often been called upon to witness the breaking of the protective wall and, a few hours later, the death of the patient from general septic peritonitis.

There are three types of the disease: First, the acute; second, the subacute; and, third, the chronic. The duration in all the types varies from one day to several years, and the subacute and chronic forms may undergo an acute termination at any time.

[1] Read before the Michigan State Medical Society, July 10, 1890.

[1] Abdominal Surgery, second edition, page 72.

The following are the chief symptoms: Pain, generally commencing and continuing in the right iliac region, and varying in intensity and area according to the condition within: tenderness, usually pronounced; rapid wiry pulse; temperature low—101°–102°; pinched features; decided sweating; occasionally vomiting; tympanites, generally marked: frequently œdema of the iliac region and inguinal tumefaction. These symptoms and signs vary with the type of the disease. Frequently no tumefaction can be detected, and I have seen well-marked cases, such as are mentioned by Pepper, which manifested no dulness on percussion.

The gravity of the prognosis depends upon the degree and kind of mischief present. But how can this be accurately determined? I maintain that it is practically impossible to make this all-important differentiation. Pepper has said that "if the prominence, induration and dulness are marked, delay is safe, especially if rectal examination does not indicate any fulness on the right side of the roof of the pelvis." "If this is present," he goes on to say, "it indicates an amount of exudation which will probably end in abscess and is a strong indication for operation." And yet in the case about to be reported rectal examination indicated absolutely nothing; but the operation revealed a condition of affairs amply justifying the procedure, and showed the location of the abscess to be approachable by the rectal route.

Rules for the employment of operative procedures, unless it be in the purely chronic forms, cannot be laid down. Our judgment, based upon personal experience and the results of other operators, must be the guide. The practice of using the aspirator needle in order to establish the presence or absence of pus cannot, in my estimation, be too strongly condemned.

There is one class of cases—the chronic—which should, perhaps, receive further notice in this paper: cases where successive attacks are followed by periods of immunity, frequently lasting for several months. These cases are associated with a chronic disorder of the appendix, without perforation, which undergoes exacerbations and remissions from slight and sometimes unaccountable causes, thus placing the life of the patient in constant jeopardy. This matter has been freely discussed and there is still a difference of opinion in the profession concerning it. Shrady is one of others who believe that each recurrence often, and perhaps generally, tends to remove still further the possibility of a rupture by adding to the mass of protecting inflammatory exudate already present. There is also reported a type of cases where, after repeated recurrent symptoms, the patients having died of other causes, post-mortem inspection has revealed nothing whatever abnormal in the appearance or condition of the appendix.

But while such testimony cannot be gainsaid, there is plenty of evidence, on the other hand, in regard to cases where both ante- and post-mortem examinations have shown free appendices distended with pus and ulcerated in spots through the mucous to the peritoneal coat. No remarks are necessary in regard to the wisdom of operating in such instances. The question is: How are we to diagnose them? How to differentiate?

There is but one way open to us, and that is in cases of doubt to make an exploratory incision. It does not follow that because the abdomen has been opened in these chronic cases the appendix should necessarily be removed. In such cases as the above it is, of course, the only thing to do; but where the organ is firmly imbedded in a mass of adhesions, requiring difficult and tedious dissection, with imminent danger of tearing into a contiguous coil of intestine, it would be wiser to refrain from attempts at excision, and to be satisfied with flushing, and establishing proper drainage.

A history of two or three recurrences in any particular case would not justify operative interference; but repeated attacks, sufficient in number to embarrass seriously business obligations, or occurring in individuals whose duties frequently compel their sojourn in regions where surgical skill cannot be obtained, particularly if we realize the liability to hepatic abscess and phlebitis from the continued presence of a disease-nidus connected with the portal system, justify an intermediate operation. Such is the doctrine of Weir, Bull, and others, and I consider it sound philosophy.

The medical treatment of acute and subacute cases I leave untouched; but the operative, as well as the medical details will be mentioned in the report of the case which follows:

S. M., aged eighteen years; employed in a furniture factory; taken sick on the afternoon of April 13th. The next morning the family called Dr. H. E. Locher, who kindly furnished the following report:

"Was called to see the patient on the morning of April 14th, and found him suffering from severe pain in the right iliac region. Patient stated that the pain had come on suddenly after dinner the day before. Pulse 105; temperature 101° F. He had vomited frequently during the previous afternoon and evening. Examination located the pain in the ileo-cæcal region. I questioned the patient closely in regard to his actions prior to the seizure, whether he had done any heavy lifting, wrestling, etc.; but the only fact of importance was a history of having gone some distance from the factory during the noon hour, in consequence of which, fearing that he might be late in getting to his work again, he ran very rapidly part of the way back. Shortly

after returning the pain came on and grew more and more intense until it compelled him to leave his work and go home in the middle of the afternoon.

"Judging from the history and circumstances of the case, the diagnosis pointed to some form of intestinal obstruction near the ileo-cæcal valve, possibly a volvulus, or to a commencing appendicitis from the lodgement and impaction of partially digested or other matter in the appendix.

"Treatment at that time was as follows: Bismuth subnitrate and Dover's powder in moderate doses every four hours and potassium bromide, gelsemium, and morphine oftener. Hot fomentations over right iliac region. Ordered a small dose of castor oil to be given if pain became markedly less.

"*April 15*. Patient considerably better; continued treatment as before; also ordered mustard poultice to affected region and more castor oil, inasmuch as the bowels had not yet moved. Patient suffered much during the afternoon and evening, which was thought might be due, in part at least, to the effect of the oil. Pulse at evening 110; temperature 101° F.

"*16th*. Was much better; bowels had moved three times during the night and tenderness in the affected region was considerably diminished. Pulse 96; temperature normal; tongue had been slightly reddened, but this morning had a white coating. Bismuth and Dover's powders continued and patient ordered to remain in bed, inasmuch as several attempts at getting up had materially increased the pain.

"Did not see patient again, but was told by a member of the family on the next day, April 17th, that the boy was much better."

On the evening of this day, April 17th, Dr. Eugene Boise was called to attend the case. He states that he found the patient with a temperature of 101.5° F. and a pulse of 110; dry tongue; abdomen swollen and tender; great pain in region of appendix; pinched features, etc. Morphine, quinine, hot fomentations, and general supporting treatment ordered. Appendicitis was diagnosed.

Matters ran along until the afternoon of April 19th, when the writer was called by Dr. Boise. The diagnosis of perforative appendicitis was confirmed and operation advised.

As the family desired the counsel of Dr. George K. Johnson before proceeding to such a measure, the matter was deferred and a consultation was not held until the afternoon of Sunday, the 20th. This consultation resulted in the opinion that if patient was not better by morning the abdomen should be opened. Morning came, the patient was no better, and preparations for the operation were made. Thus, valuable time had been lost, and the operation was undertaken without much hope of saving the patient's life. However, surgery offered a better chance than medicine, and hence was chosen in the dilemma.

Operation on morning of April 21st. The physicians present were Drs. George K. Johnson, Eugene Boise, D. M. Greene, R. H. Spencer, C. A. Johnson, and the writer, all of Grand Rapids, and H. Boss, of Zeeland, Mich.

Through the courtesy of Dr. Boise and with his valuable assistance, as well as that of the other physicians present, the writer operated.

Patient was anæsthetized with ether in his bed, and then transferred to a table in the adjoining room. The abdomen was cleansed with hydronaphthol soap, shaved, douched with bichloride solution (1 to 2000), and surrounded by towels wrung from hot sublimate solution. Chloroform was then substituted for ether. An incision three inches long (afterward increased to four inches) was made over the cæcum, a little external to the right linea semilunaris. The different layers of tissue were divided by shallow strokes of the knife or upon the director. Hæmorrhage was slight and was controlled before entering abdomen. Peritoneum nicked, carefully enlarged to admit the index finger, and then divided with a probe-pointed bistoury to the extent of the wound. Great thickening of the peritoneum was observed.

The small intestines and omentum were strongly bound together by inflammatory exudation, necessitating careful tearing with the fingers to effect separation. At this point a gush of pus indicated the proximity of the expected abscess.

A strong fæcal odor was manifest. The point where the pus had welled up was cautiously enlarged and the cavity of the abscess freely opened. Upon passing the finger into the sac a foreign substance, about the size of a small hazel-nut, and which afterward proved to be a fæcal concretion, was felt lying loose in the cavity.

Considerable difficulty was met with in the recognition of the various tissues on account of inflammatory deposits and the quite free oozing of blood, which resulted from the separation of adhesions in spite of the great gentleness with which this was done. All, however, was soon made clear, and the appendix was found lying upon the inner wall of the abscess, as is the rule in these cases. The distal half of the organ, as a result of destructive inflammation, was absent, and the fæcal concretion which had obstructed this portion of the appendix was free, as stated above, at the bottom of the sac. The proximal half of the appendix was freed from its adhesions, cut off close to the cæcum and the stump inverted and disposed of by the application of three Lembert sutures of fine aseptic silk.

Four gangrenous masses which had been observed, three of omentum and one of abscess-wall, were ligated with aseptic gut and removed.

Throughout the operation hot, boiled water was in almost constant use for flushing the sac and also the general peritoneal cavity, for a small portion of the appendix was within the abscess, thus communicating with the general cavity.

After tying a few vessels and flushing with hot water to check oozing, and to wash out any remaining débris, the boiled water returned quite colorless. Two rubber drains were then placed in position (one in abscess sac and the other in the general cavity) and the incision closed by a combination of aseptic silk and catgut sutures passed through all the layers of the abdominal wall, including the peritoneum. Several superficial sutures of catgut were taken, the

cavities were once more flushed with boiling water, and the usual antiseptic dressings applied.

The patient's pulse, at the close of the operation, was 150. He was put in bed, hot bottles placed at his feet, and morphine, atropine, and brandy administered hypodermically.

When consciousness returned he was ordered fluid extract of digitalis, 1 minim hourly, a half-teaspoonful of Armour's Beef Extract in a little hot water, every half hour, and a teacupful of warm milk, with a tablespoonful of brandy, every two hours.

At 5 P. M., four hours after the completion of the operation, his pulse was 130; temperature not taken.

At 10 o'clock P. M. pulse the same; nourishment and medicine had been retained; his skin was warm; facial perspiration much diminished. When asked how he felt he replied: "Better."

April 22, 8 A. M. Temperature during previous night ranged from 102° to 103°; pulse remained at 130 in spite of full doses of digitalis. Nourishment and stimulants were still retained. Urine was passed involuntarily several times during the night. 12 M. condition unchanged. Catheter introduced and considerable urine withdrawn. Patient was under the influence of morphine and was somewhat "flighty;" wound had a bad odor; cavities washed out with hot Thiersch's solution and fresh dressings applied. Patient evidently sinking. Death occurred rather suddenly at 2 P. M.

There was one serious objection to the performance of this operation, and that was the necessity of using a stuffy, upper room which could not be made aseptic. The parents would not tolerate the thought of having their son removed to a hospital.

I have reported this case because I deem it the duty of surgeons to make known the results of their operations regardless of the results, for otherwise statistics would be worthless.

In conclusion:

Although cases of perforative appendicitis do occasionally terminate favorably by means of adhesions to and discharge through neighboring hollow viscera, or by external pointing, can this very fortunate turn of affairs be counted upon in any individual case of the disease? Is it not wiser, where the symptoms do not abate in three or four days, to give the patient the benefit of surgery in time by performing an early laparotomy?

The operation itself, under antiseptic details, although not devoid of danger, is quite safe, and if nothing more is needed than the flushing of the abdominal cavity with hot, boiled water good cannot but be accomplished.

On the other hand, if the condition be such as to show the probability of a fatal termination if left to medical treatment alone, we have the advantage of an early opportunity to attack the disease before inflammatory and septic shock have so exhausted the patient as to render our endeavors to save him from death vain and ineffectual.

Consideration of the facts associated with the foregoing case have caused the crystallization, in my mind, of two salient ideas:

1. The patient should be treated in a well-equipped hospital, if possible.

2. The operation should be performed early.

SURGICAL AND MECHANICAL THERAPEUTICS IN DISEASES USUALLY TREATED BY MEDICINE ALONE.[1]

By GEORGE M. KREIDER, A.B., M.D.,
OF SPRINGFIELD, ILL.

No fact is more patent nor more pleasing to the intelligent observer of our profession than the ever increasing use of surgical and mechanical appliances for the treatment of diseases formerly treated by medicines alone. The too great reliance which was placed on drugs in former years led to the most absurd theories concerning their action and influence, and resulted, after homœopathy and kindred dogmas had had their day, in a therapeutic nihilism quite as absurd and cruel as they. Mechanical methods of treatment are slowly but surely trenching on the domain of medicine, and together with that other benevolent giant, prevention, are destined to narrow down the effective use of drugs to a very small circle and to a very small number. Thorough knowledge of a disease simplifies the treatment of it. Scientific methods of investigation, and instruments for testing diseased organs and tissues supply this knowledge, and these methods and instruments are no longer ridiculed, but are the common property of all intelligent practitioners. One of the apparent dangers of practice now is, not that we are too conservative but are rather too prone to take up and laud new treatments before they have stood the all-important test of time.

All dropsies were formerly treated by diuretic or purgative medicines, later by palliative tappings, but now the wonders performed by the removal of the cause of many dropsies, ovarian tumors and kindred abdominal growths, are so common that they are no longer matters of discussion. I do not intend, in this paper, to touch on these well-known topics, but there are other methods of mechanical relief which are not so well known and of which I may be permitted to speak. For example, who would have thought a few years since of treating erysipelas by anything but large doses of drugs, or of relieving neuralgias of the fifth nerve by anything except hypnotics or sedatives. Hysteria was formerly the name given to all of the numerous nervous complaints of females, and was a term

[1] Read before Illinois State Medical Society, May, 1890.

of ridicule. It received no treatment, and its victim little sympathy, but now we find that mechanical treatment will remove most of the cases, and it becomes an interesting study to discover the cause and the methods of relief. It will be my object in this paper to give a *résumé* of the recent application of treatments other than medical which I have myself used and which I believe are too often overlooked and ignored.

First, let us take that most universal symptom of disease which we are called upon to treat—fever. The drug treatment of this has passed successively from quinine to antipyrine, from antipyrine to antifebrin, from antifebrin to phenacetin, and so on, aconite and veratrum included, to an unending number of aspirants for its complete conquest. For some years I have ceased to rely upon these drugs for the reduction of fever, or at least have only used them under protest and as adjuncts to the use of water, either by sponging, bathing, or the ice-coil. I need only mention here that my ideas on these methods have been fully detailed in other papers, namely: "The Treatment of Fever by the Ice-coil:" the "Treatment of Puerperal Fever by Disinfection of the Uterine Cavity and the Use of the Ice-coil;" and the "Treatment of Pneumonia by Tepid Baths." Since the reading of the last-named paper at Jacksonville I have treated all the cases of pneumonia coming under my care by bathing or sponging, and can reiterate with emphasis the conclusions then reached. I have also had renewed proofs of the value of the ice-coil in cases of fever in which it was either impossible or impracticable to use the bath. Up to the present time I have treated eighteen cases of puerperal fever by the method mentioned above, with two deaths.

At the last meeting of the Illinois State Medical Society the late lamented Dr. Alexander Darrah read a valuable paper on the prevention and treatment of summer diseases of children by cool baths, which confirmed me in my estimate of the value of baths. Other mechanical procedures in these cases of summer complaint may be used with good effect. For example, last June I was called to see a four-year-old child in the last stages of dysentery, which had been carefully and skilfully treated by the attending physicians. She had a dry tongue, bloody stools, high fever, and was greatly prostrated. Under these circumstances I suggested, and with the aid of her attending physicians carried out, thorough irrigation of the colon with a solution of boric acid, followed by a solution of tannic acid. From the time this treatment was commenced the child began to improve and made a perfect recovery. A case of more than usual interest where irrigation was effective in disease of another portion of the alimentary tract, is the following:

Mrs. B., aged sixty-nine, had suffered for some weeks with symptoms of gastric ulcer. For several months she had experienced burning sensations in the stomach, coming on a few hours after eating. Later she had repeated attacks of vomiting of alkaline mucus. These attacks became more and more frequent and protracted. Nausea was a constant symptom day and night unless she was quieted by medicines. Finally she vomited bloody mucus and clear blood, and her condition became extremely serious. She rejected all food, and life was sustained by enemata. To quiet the intense pains six ounces of chloroform were inhaled every twenty-four hours. At this time my advice was given by telegraph to irrigate the stomach. Irrigation was delayed by the fear of her attending physicians that she was too weak to endure the operation of passing the tube to the stomach. As a last resort lavage was finally made, and from the hour of its employment improvement in her condition began and continued, after repetitions of the lavage, to her complete restoration to health.

A return of the symptoms some eleven months later does not vitiate the value of the treatment. I have been urged by those acquainted with the history of this case to make known this treatment of gastric ulcer, cancer, or dilatation for the benefit of those members of the profession who are possibly not cognizant of its value. Dr. Bodman, of Toledo, O., who was acquainted with the history and treatment of this case, writes that it certainly saved her life.

The attention of the profession has been frequently called to the fact that a tight prepuce may so affect the nervous system as to produce reflex disturbances of a serious nature. I have had some interesting cases of nervous disturbances arising from this source, which were, of course, relieved by the operation of circumcision. In one case talipes varus existed, but disappeared within a week after circumcision. In another case there was partial paralysis of the lower extremities, which was recovered from soon after the operation. Slighter forms of irritation from this cause are so often overlooked and the patients treated for something else, that I make it a rule to examine all male children suffering from nervous disturbances, for this disability.

A frequent cause of nervous disturbance is to be found in errors of refraction. In a paper read at a meeting of the District Medical Society I detailed some of my experiences with this difficulty and its relief by properly fitted glasses. Since reading that paper I have had one case in which, apparently, spasm of the bladder was caused by eye-strain, or at least, this symptom has become less frequent since the proper glasses were used. In another instance chorea was cured by the same means.

Speaking of neuralgia reminds me of the numer-

ous cases which I have seen, where suppuration of the middle ear was treated for neuralgia until the mastoid cells were invaded and dangerous complications existed. Of course these mistakes were due to ignorance or carelessness, but such ignorance is frequently shown and serves me to emphasize a point which should be made prominent, viz.: that all practitioners should be so familiar with the instruments for making exact diagnoses, and with the proper mechanical treatment, that such mistakes may become impossible.

Many of the diseases of the ear can be relieved by mechanical treatment only, and a majority of the operations are such as the general practitioner should be able to perform. Perhaps he may not operate so rapidly or skilfully as the specialist, but just as effectually.

A change in the treatment of erysipelas has already been hinted at, and the new method is doubtless well known to most of my readers. Instead of large doses of chloride of iron, an anæsthetic is given, the affected part is surrounded by slight scarifications, and an antiseptic lotion is applied. By this treatment the disease can usually be made to disappear within twenty-four hours.

Speaking of diseases of the skin recalls the importance of destroying all suspicious growths in their very incipiency. Every surgeon has had patients who have been advised by their family physician to refrain from having anything done with excrescences or tumors, which have afterward gone on to the formation of most painful and dangerous cancers. Very few growths can be said to be without danger, and even if they are harmless, they usually produce mental worry, which causes the patient to resort to all sorts of quacks and quack remedies for his relief. By a full statement of the possibilities of the case the ready consent of the patient to their removal can usually be gained, while at the same time any groundless fears may be calmed by the assurance of the lack of danger if removed early. At the present time cancers and similar growths can be best cured by being extirpated in the very earliest stage, and this possibility should not be denied to suffering humanity by such advice as "Do not hurt the growth until it hurts you," or "Let well enough alone."

Diphtheria, tonsillitis, and their results can usually be better treated with the assistance of mechanical methods than by internal medication alone. In tonsillitis the endeavor should be to disinfect each crypt by passing to its bottom a fine probe coated with antiseptic lotion, and, when a case is thus early treated, I believe much serious trouble can be prevented. After the early stage is passed I find that the steam spray can be used with great advantage. I have the record of one case of diphtheria treated with success in this way. That it was genuine diphtheria was proven by the paralysis which followed. A most interesting case of this character was that of my colleague, Dr. O. B. Babcock, of Rochester. While attending a case of fatal scarlatinal diphtheria he himself became infected with the poison. In a very short time, despite the use of medicines, douches, syringes, sprays, and incisions, his condition became dangerous. The soft palate touched the pharynx, and the œdema of the tonsils was so great that, notwithstanding removal of the uvula, he was left without adequate breathing space. The incisions and the stump of the uvula remained perfectly dry, and the tissues were as tense and brawny as a board. In this extreme condition I secured a gasoline stove, a tea-kettle, and a piece of tin spouting. The stove was placed near the bed and the steam conveyed through the spouting in large quantities to the patient's mouth. So great was the resolving and relaxing effect of the hot vapor that very soon the exudate came through the cut surfaces in large quantities and in due time a cure was effected. By the use of medicines alone this case would undoubtedly have been fatal. I cannot leave the discussion of this region without referring to the excellent progress which has been made in the treatment of catarrhs and nasal diseases by the various modern operations and mechanical procedures. How many cases of deafness, scrofula, anæmia, and narrow chest can now be cured by the removal of adenoid vegetations in the pharynx and of hypertrophied tonsils which medicines will absolutely fail to relieve? I have in several instances been called on to treat cases of chronic hoarseness which were due to growths on the vocal cords, and were, of course, curable by local treatment only, and yet had been treated for months and weeks by internal medicines. O'Dwyer's inventions, and the tracheal tubes used in tracheotomy, are modern mechanical improvements in the treatment of diseases which were formerly palliated by medicines alone.

Pleurisy which has gone on to effusion is now no longer treated experimentally for the reabsorption of the fluid, but the cavity is drained by surgical and mechanical means, and a failure to cure is the exception. Typhlitis and obstruction of the bowel are boldly attacked, and although my own record in this class of cases is not encouraging, I recognize the fact that my failures are due to too late operations, or to the difficulties in diagnosis or treatment which others have overcome and which I hope to conquer in the future.

The same statement may be made concerning my experience in the diagnosis and treatment of brain- and spinal-cord diseases. I have endeavored to apply the proper treatment in two cases of brain disease, one of which I here report.

Case.—Mr. H. E., aged thirty-two years, clerk. Seen with Dr. Ryan. On rising from a stooping position in a cellar, his head struck a timber with great force, and he was stunned and nauseated by the jar. He continued at work for some days, but was obliged to stop for a part of each day because of pains and dizziness. About ten days after the receipt of the injury, at an early hour of the morning, we were called to see him. The family had been aroused by hearing him fall heavily on the floor, and when they reached him he was in a stupor from which he could not be awakened. No history of the injury could be obtained at this time, but later the history and symptoms made a diagnosis of abscess possible. The symptoms were headache on the right side of the head, vomiting, paralysis or weakness of the left side, hesitation in answering questions, involuntary passage of urine and fæces, and gradually increasing coma. There was a choked disk on the right side. As the paralysis of the side was general, we were unable to locate the abscess. The patient being in a state of profound coma, the cranium was trephined over the motor centres and a hollow needle passed in different directions. The pus was either not reached or else it was so thick that it would not flow, and the patient died unrelieved. The post-mortem examination on the following day revealed a large abscess in the region of the parieto-occipital fissure which had broken into the third ventricle and caused death.

Did time permit I might detail the benefits of suspension and other mechanical treatments of spinal and spinal cord diseases; the effects of hot water in gynecological practice; of early incisions in bone diseases, and of numerous other measures not less worthy of discussion, but I will conclude with the following summary:

1. That mechanical and surgical measures are the most certain in our armamentarium and are only now assuming their proper position.

2. That when called to see a case of disease the first aim of the practitioner should be to determine, by proper examination and research, whether some mechanical or surgical appliance cannot be used in conjunction with or in place of medical treatment.

3. That the "do something" which this action implies will be more uniform in its results, more successful in its curative effects, and more pleasing to the patient than the "think something" treatment, which tries every medicine by turns and nothing long, and hopes for beneficial results.

4. That the ability to use exact appliances for the examination of patients and treatment of disease should be possessed by every one attempting to practise, and that this ability is only to be obtained by preliminary training and clinical instruction.

5. That treatment of disease in this manner has a tendency to elevate the profession in the eyes of the public, and to dissipate nonsensical sects which divide the profession and waste its energies.

CLINICAL MEMORANDA.

OBSTETRICAL.

A Plea for the Term "Heart-failure," with Notes of a Case.—Of late, registry bureaus, coroners' clerks, and closet pathologists, have refused to accept the term "heart-failure" as a sufficient cause of death, and the physician who dares to sign his certificates in such a manner is regarded as uncertain in his diagnosis and a stranger to modern pathology; but, on behalf of clinical experience, I venture to make a plea for the actuality of heart-failure, without pathological lesions sufficient to explain it, and I report the following somewhat unusual clinical history and result of autopsy, in support of the heresy.

Mrs. C., a multipara, aged forty years, who had not required the services of a physician in any capacity since her last confinement, found herself pregnant January, 1889, with her third child. On Wednesday, July 17th, I was called to see her, and found her with preparations made for a confinement, which she had expected to occur between the 15th and 20th. Questioning revealed that there had been a few very slight pains, active fœtal movement, abundant "show," and the passage of some clots. There had been œdema of limbs, but it had disappeared; there was no vertigo, nor vomiting; urine was passed freely; the pulse was 76, full and strong, and the respiration was clear and normal. Examination revealed obliteration of cervix; a closed but dilatable os; the fœtus presenting by the head, and the uterus well contracted upon its contents. With instructions to the patient to send for her nurse and for me, at the first appearance of actual labor, I left her, and was called again on Friday, about 6 P.M.

At this visit I found the os about the size of a silver quarter; head presenting; membranes intact, and I felt what seemed to be a thickened anterior lip of the os. The patient had felt some slight pains, and said she had had very profuse bleeding an hour or two before. Her color was good, and her pulse normal. Instructing the nurse to keep careful watch over the symptoms, and particularly for bleeding, I again left, to be re-summoned about 10 P.M., from which time I remained with the patient.

Patient had complained of faintness, profuse bleeding, and slight infrequent pains. Examination revealed several large clots about the os, which was dilated to the size of a silver dollar. Within the anterior margin of the os was found a soft, smooth mass, which was readily pushed up between the head and the anterior lip. Diagnosis: marginal placenta prævia.

Consultation was called, but on the arrival of the consultant the head had been descending upon the os, so that the thickened mass was not discoverable; and, as bleeding had stopped, and the patient's condition was good, it was not deemed expedient to enter the uterine cavity for purposes of exploration. Pulse 72 and strong; uterus conforming well to its contents. Fœtal movements felt by patient. I ordered fluid extract of ergot, one drachm, and tamponed the vagina. From this time, 12.30 A.M., labor progressed. Pains were of short duration, but increased in frequency and strength. No hæmorrhage; patient warm and comfortable. Complained of some faintness, but there was no "yawning,"

and the pulse remained so full and slow, that we were inclined to regard the amount of hæmorrhage as having been exaggerated.

At 3 30 A.M. the patient was doing well, the pains increasing in power, and characteristic of the second stage of labor—patient somewhat hysterical. Fœtal head found descending. At 4 o'clock, on examining the patient, the head was found in the hollow of sacrum, and the perineum relaxed. About this time the pains suddenly ceased, the patient asked for a drink, and complained of feeling faint. Pulse fading, extremities cold, countenance distressed and pale. Patient put her hand over the region of the heart. Heat was promptly applied to the extremities and spine, the pillows were removed, and brandy and aromatic ammonia given. The first heart-sound could not be heard, the breathing became more rapid, and the patient suddenly died about 4.15 A.M.

To save the child, version by the feet was then speedily and easily performed, but the child was dead. The placenta was purposely left within the uterine cavity.

Autopsy, made at 4 P.M., by Dr. J. W. Brooks, coroner's physician. Heart normal. Uterus contained no more blood than would normally appear after abstracting a child from a non-contracting cavity. The placenta was still adherent, and the inferior margin stretched slightly across the anterior lip of the os. The only pathological lesion was an interstitial nephritis, the capsule being somewhat adherent to the kidney.

The physician who performed the autopsy, declared that the lesions were suggestive of either coma or convulsions, but the symptoms were against such a conclusion. The patient was conscious to the last, and not a muscle was at any time convulsed (unless it were the heart).

Now, of what did the patient die? Not from bleeding, pure and simple, for the pulse remained good for two and more hours after bleeding had ceased. There were no evidences of blood-poisoning—nothing but giving out of the heart's power after a not excessive hæmorrhage. Respiration even continued after the radial pulse was lost to the touch. To elucidate our pathology, this patient ought to have had coma or convulsions, but three witnesses failed to observe either condition; or she ought to have had some valvular lesion, but there was none. However, her heart *did* grow weak in its action, and she *did* die.

FRANK W. THOMAS, M.D.

6 MT. AIRY AV., GERMANTOWN, PENNA.

MEDICAL PROGRESS.

Thiersch's Method of Skin-grafting.—DR. IVAN FOMIN, of St. Petersburg, reports eighteen cases in which he used Thiersch's method of skin-grafting (*Vratch*, No. 11, 1890). The author carried out the method as follows: The surface of a crural ulcer, for example, is dressed with compresses wrung from a 1-to-5000 solution of corrosive sublimate until complete cleansing of the granulating surface has taken place—usually in from three to seven days. On the day of the operation the entire limb is washed with soap and water and an antiseptic lotion, after which a syringeful of a 4-per-cent. solution of cocaine is injected in the neighborhood of the ulcer, and the latter is carefully scraped away, with a sharp spoon, down to the muscle or fascia. After this a bandage to arrest hæmorrhage is applied and left in place for from half an hour to two hours. Next, thin cutaneous strips, measuring about five or six inches in length and two and a half in width, are sliced, with a sharp razor, usually from the patient's arm, which should have been thoroughly disinfected. This step of the operation may be rendered painless by giving a hypodermic injection of cocaine. The strips are then moistened with a 1-per-cent. solution of carbolic acid and placed on the ulcer, not only the entire surface being covered, but the healthy skin slightly overlapped. The grafts are then carefully dried with absorbent cotton, dusted with a thin layer of iodoform, and covered with fenestrated strips of protective, which overlap each other like tiles. The whole is then dressed with antiseptic material and the limb immobilized.

The results obtained by Dr. Fomin are excellent—even most extensive and obstinate ulcers healing in a few weeks.—*Annals of Surgery*, July, 1890.

Diabetes following Resection of the Pancreas.—VON MERING and MINOWSKI have undertaken a series of experiments upon extirpation of the pancreas as a cause of diabetes (*Archiv f. experimentelle Pathologie*). The operations were performed under strict antiseptic precautions, and were followed by permanent diabetes, resembling the severest form of the disease in man. The animals became very hungry and thirsty, but, though well fed, emaciated rapidly. If even a small part of the pancreas was allowed to remain, diabetes did not follow, showing that the disease was not due to traumatism, but to the absence of the pancreas. The authors think that their experiments prove that one of the functions of the pancreas is destruction of sugar, either if introduced from without or formed within the body. As an additional proof of this, if grape sugar is given to an animal which has lost the pancreas, the whole of the sugar can be recovered from the urine.

DOMINICUS, of Italy, has also made a series of similar experiments, and with much the same results, but he concludes that the diabetes is caused only indirectly by the loss of the pancreas, the immediate cause being the disturbances of digestion produced.—*Centralblatt f. klinische Medicin*, June 7, 1890.

Prescription for Vomiting of Pregnancy.—According to the *Canada Medical Record*, M. HUBERT uses the following mixture to relieve the vomiting of pregnancy:

R.—Tincture of iodine	. .	6 drops.
Potassium iodide	. .	1½ drachms.
Distilled water	. .	4½ ounces.—M.

One teaspoonful three times daily.

Treatment of Erysipelas.—The *Weekly Medical Review* quotes the following prescription used by KOCH in the treatment of erysipelas:

R.—Creolin	. . . . .	1 part.
Iodoform	. . . . .	4 parts.
Lanolin	. . . . .	10 " —M.

This ointment is painted on the diseased parts by means of a soft brush and covered with gutta-percha tissue.

Hallopeau applies compresses saturated with a 1-to-20 solution of sodium salicylate, and, to prevent evaporation, covered with impervious tissue.

Wölfler uses mechanical compression by means of adhesive-plaster straps, applied on the healthy skin and surrounding the diseased area.

The Treatment of Uterine Cancer.—Mr. F. B. Jessett writes (*British Gynecological Journal*, May, 1890) upon the treatment of cancer of the uterus as follows:

Palliative treatment is adopted in cases of advanced disease. By means of it much may be done to relieve suffering, to arrest the rapid progress of the disease, and to improve the general health. The vagina should be thoroughly syringed with "sanitas" or some other antiseptic lotion through a full-sized speculum; then, with pieces of cotton-wool, the cavity should be wiped out as far as possible, removing all débris and loose sloughs; a tampon of cotton-wool soaked in equal parts of pinus canadensis and glycerin, or smeared with an ointment composed of one ounce of sanitas oil, ten grains of chloride of zinc, and an ounce of vaseline, should be introduced into the cavity; this should be used night and morning, the vagina being syringed out each time, and the cavity wiped with cotton-wool before the insertion of fresh tampons. By adopting this simple plan of treatment the sloughs become dislodged and a clean ulcerated surface exposed. All offensive smell will disappear, and the pain and vesical irritation be much decreased. The disease will be considerably retarded in its growth, the patient's appetite returns and the general health improves, doubtless owing to the non-absorption of the poisonous discharge. Perfect rest should be insisted on, and the general health attended to by the administration of appropriate tonics; and if pain is present and prevents sleep, small doses of morphine may be advantageously given. It may be added that no success has attended the use of any drug given for the purpose of arresting the disease.

In attempting a *radical* cure the case must have been seen early, while the uterus is still freely movable, and before the vaginal walls have become involved. When the vaginal portion of the uterus is alone affected, amputation of the cervix by means of scissors is recommended. Caustics in this, and other forms, are unreliable.

When cancer involves the cervical portion of the canal, the disease should be removed by cutting away a conical portion of the uterus beyond the disease. This method the author prefers to the total extirpation of the organ—an operation which he cannot at present bring himself to adopt. Total extirpation may, however, be performed in suitable cases when disease in the body of the uterus has been early recognized. In removing the conical portion the operation closely resembles the high amputation of the cervix. The vagina around the cervix is snipped with blunt-pointed scissors, and the vaginal mucous membrane and tissues beneath pushed up as far as possible. The uterine tissues are then divided by short snips with the scissors, the part to be removed being, at the same time, firmly pulled down by a vulsellum. In this way the diseased tissues may be removed, even to the fundus.—*Medical Chronicle*, July, 1890.

India-rubber Iodoform Plaster.—The *American Druggist* quotes the following prescription for the preparation of a 20-per-cent. iodoform plaster:

R.—Dammar resin	. . . .	15 parts.
Benzoated tallow	. . . .	30 "
Lanolin	. . . .	20 "
Caoutchouc	. . . .	5 "
Glycerin	. . . .	10 "
Iodoform	. . . .	20 "

The resin is melted by heat, then the tallow is added, and the whole is strained through several layers of gauze. With this mass, while still liquid, the caoutchouc in solution and the lanolin are incorporated. The iodoform is triturated with the glycerin, and added after the mass has somewhat cooled.

The caoutchouc solution is prepared by dissolving flake India-rubber in five times its weight of benzine.

Hydronaphthol as an Intestinal Antiseptic.—Dr. J. Mitchell Clarke (*Practitioner*, July, 1890) reports a series of experiments to determine the influence of hydronaphthol on digestion and its value as an antiseptic in the treatment of intestinal diseases. He concludes that to patients on an absolute milk diet the drug can be given without fear of seriously interfering with digestion; but that if gastric disturbances are produced they are probably due to retardation of peptic digestion and to the accumulation of curds in the stomach. Under the latter circumstances, perhaps under all, it is advisable to give the drug in pill-form coated with keratin in order that it will not be set free before reaching the intestine. For adults, Dr. Clarke thinks a dose of two or three grains given every two hours sufficient. In diarrhœas the intervals may be increased after the first few doses. For children under one year the dose is half a grain.

Five cases of typhoid fever were treated with hydronaphthol by the author. All did well, though two were severe, and at the beginning had profuse diarrhœa which ceased soon after the treatment was instituted. In two less severe cases diarrhœa was also quickly checked, and it was noticed that the stools soon lost their offensive odor. In the treatment of the summer diarrhœas of infants the drug also seemed to be of benefit. In one case of dysenteric diarrhœa which had lasted for five weeks with from twenty-five to thirty stools daily, a milk diet and the administration of hydronaphthol was followed in four days by great improvement, the stools being reduced to four daily. In thirteen days the patient was cured.

One case of tubercular diarrhœa and several cases of ordinary diarrhœa from indiscretions in diet also yielded to the administration of the drug.

[It is obvious that the observations are too few for positive conclusions, but the apparently good results certainly warrant a more extended trial of hydronaphthol as an intestinal antiseptic.—Ed.]

The Treatment of Burns of the Eye.—Dr. A. Trousseau (*Recueil d'Ophtalmologie*, No. 8, 1890) recommends, in burns of the eye by acids, free irrigation with cold water, followed by compresses soaked in an alkaline lotion or Vichy-water, and placed over the half-closed

lids. If the pain is severe the compresses should be alternated with ice-poultices, which give great relief and often prevent inflammation. In injuries caused by caustic alkalies, the cornea and conjunctival *culs-de-sac* must be thoroughly irrigated and foreign bodies carefully removed. The after-treatment should consist in copious instillations of a ½-per-cent. solution of carbolic acid. Lime burns are especially serious in their subsequent effects, as they rapidly destroy the corneal tissues, and by their escharotic effect on the conjunctiva are apt to produce contraction and symblepharon. These sequelæ may, to a great extent, be prevented by freely washing with a very dilute acid solution, or by Gosselin's method of syringing the eye with sugar-water, with the object of forming a soluble saccharate of lime.

Burns by molten metal are best treated by the removal of metallic fragments, which are usually firmly embedded in the tissues, followed by compresses soaked in boric or carbolic acid lotion. In every case a drop of atropine solution should be used.—*Medical Chronicle*, July, 1890.

The Treatment of Diphtheria.—In an interesting and able paper upon the treatment of diphtheria, DR. MANUEL HERRERA, of Guanajay, Cuba (*Revista de Ciencias Médicas*, Havana, April 20, 1890), strongly condemns the removal of the false membranes, even if the larynx is involved. For the treatment of the disease he relies on general and local measures, and advocates the following, as leading to the best results. He seldom uses ipecacuanha, but usually employs quinine and calomel continuously in doses of fifteen grains and one and a half grains, respectively, during the twenty-four hours, stopping the latter drug when the first symptoms of ptyalism appear. The use of calomel, however, is resumed; and should the mercurial effects return, they are checked with chlorate of potassium, internally; and thus a continuous mercurial saturation of the system is maintained, without the danger of a stomatitis that would, undoubtedly, aggravate the primary disorder.

Dr. Herrera particularly lays stress upon the local treatment proposed by him. For this purpose he employs iodoform, cocaine, hydrochloric acid, camphor, mercurial ointment, and extract of belladonna, with the best results. Thirty-four cases, of the worst type, reported in his article, entirely recovered under this local treatment. Dr. Herrera's prescriptions are as follows:

1. R.—Sulphate of quinine . . 30 grains.
   Calomel . . . . 3 "

Divide into ten powders, and give one every two hours until five are taken.

2. R.—Iodoform . . . . 75 grains.
   Saccharated lime . . 2½ drachms.
   Cocaine hydrochlorate . 4 grains.
   Camphor . . . . 15 "

To be dusted over the membrane, by means of an insufflator, every five hours.

3. R.—Hydrochloric acid, Distilled water, of each 75 minims.

To be applied locally, three times a day, by means of a camel's-hair brush.

4. R.—Mercurial ointment . . 7½ drachms.
   Extract of belladonna, Iodoform, of each 75 grains.

For external application.

The Modes of Administering Cardiac Tonics.—The therapeutics of cardiac affections has been greatly advanced recently, not only by the addition of numerous cardiac tonics to our list of remedies, but also by the acquirement of important details in the administration of the older remedies, by which their efficiency has been greatly advanced.

GAUTHIER, especially, has devoted himself to the study of this subject, and an analysis of his work, as published in the *Wiener medizinische Blätter* of May 22, 1890, is well worthy of notice.

As is well known, the administration of digitalis in the form of powder or pill is apt to produce vomiting or diarrhœa. The best form is that of an infusion made by macerating the digitalis leaves, and, when time permits, it is this preparation which should always be used as the one which gives the most prolonged and intense action on the heart, and which is most efficacious in producing diuresis. The infusion should be given in gradually decreasing doses. Digitalin is by no means a constant preparation, and it does not possess all the properties of the digitalis leaves. Nevertheless, the crystallized digitalin is of use where an extremely rapid action is desired, although ordinarily its action is too intense, and, therefore, dangerous, while its subcutaneous employment is extremely painful, and often produces abscesses.

Convallaria is also best employed in the form of an infusion, 8 to 10 parts being macerated in 1000 of water, to which syrup may be added, and administered the day in which it is made.

Convallarine, the active principle, may be employed in doses of ⅙ to ¾ or 1½ grains.

Strophanthus is best given in the tincture (the one officinal in the English Codex being the best) in 5-drop doses three times daily, although 10 to 20 drops may be given once or twice in the twenty-four hours in a single dose.

Adonis may be employed in the form of an infusion or decoction, or its active principle, adonidine, may be given. The infusion seems to be inconstant in its activity, and both of the watery preparations have an extremely bitter taste, which must be masked by syrup. Adonidine may be given in the quantity of from ⅙ to ⅓ grain in twenty-four hours. Its toxic action is ten times greater than that of digitalis. Caffeine is likewise a reliable remedy, provided it is given in sufficient dose, 15 to 30 grains being ordinarily required. This dose should, however, not be exceeded without great care, as in larger quantities it is not free from danger.

The salts of caffeine are nearly insoluble in water, and are, therefore, not suitable for subcutaneous injections, although the double salt—the benzoate of sodium and caffeine—is an exceedingly valuable preparation. Sparteine may be used, either in the form of an infusion or decoction of the plant; or its active principle, sulphate of sparteine, may be employed, the latter being especially valuable for its action on the heart in doses of from ¾ to 4 grains, while the infusion possesses marked diuretic properties.—*Therapeutic Gazette*, July, 1890.

DIABETES MELLITUS.

ONE of the features that will mark the present era of medicine is the earnest endeavor to classify diseases with regard to their etiology and pathology rather than to their symptomatology. Constantly do we find ourselves able to apply a more fitting and accurate name to various groups of symptoms, and to assign to them a proper place in our nosological tables. Not merely this, but only by striking at the ultimate pathological cause can the true and rational treatment be properly conceived of and instituted.

The name diabetes mellitus has answered the purpose of designating a condition the most obvious and constant sign of which is the excretion of large quantities of saccharine urine; but the comfortable idea that in *all* cases this symptom is due to disturbance of the vaso-motor supply of the liver must give place to more definite views, and undoubtedly ere long we shall find that there are many lesions capable of producing, and having as a common symptom, the excretion of sugar in the urine. In that case diabetes mellitus may occupy the same position as a diagnostic term as do other symptomatic phenomena — albuminuria, convulsions, coma, and fever.

In the *Medico-Chirurgical Transactions* for 1833 Bright reported a case of jaundice in which fatty stools occurred and "the urine had a sweet taste," and at the autopsy there was found a scirrhous mass occupying the head of the pancreas. In 1877 Longstreth exhibited a specimen of cystic disease of the pancreas from a case of diabetes mellitus, while similar cases have lately been recorded by W. T. Bull and J. A. Nichols. Many authors speak of the presence of hypertrophy and sclerosis of the pancreas in these cases. In the Middleton-Goldsmith Lecture of 1889 R. H. Fitz quoted a case, reported by Frison (*Marseille Médicale*, 1875), of multiple pancreatic abscesses which presented sugar in the urine during life.

It is clear, however, that we have not as yet arrived at the precise conditions or lesions of the pancreas capable of causing or being frequently associated with the appearance of sugar in the urine. This is shown by the numerous cases of cystic and other pancreatic disease reported by Fitz in the lecture above mentioned, wherein glycosuria was not present, while Langenhaus has lately reported a case dying of necrosis of the pancreas without the presence of sugar in the urine.

Von Mering took the initial step in the way of experimental determination of the position occupied by the pancreas in the production of glycosuria. In dogs from which he had removed the pancreas he found an abundance of sugar in the urine. That this phenomenon was not due to the withdrawal of pancreatic digestion was shown by the negative result if but a small portion of the pancreas were allowed to remain. M. Lepine went a step further. On comparing the blood of a healthy dog with that from a dog whose pancreas had been previously removed, he found an excess of sugar in the latter, which excess was much more slowly broken up than in the blood from a dog whose pancreas had not been removed. On the addition of starch to the two specimens it was found that the blood from the dog whose pancreas had not been removed produced more glucose than did the blood of the dog so operated upon. From these experimental facts he deduces the theory that, owing to the absence of a ferment produced by the pancreas, and whose duty it is to destroy sugar in the blood, glycolysis takes place to a less extent than glycogenesis, with the result of the presence of an excess of sugar in the blood and the excretion of sugar in the urine.

There must still remain, however, many cases of diabetes mellitus independent of pancreatic disease. The frequent occurrence of glycosuria in various

cerebral lesions is well known, while a sufficient number of cases of diabetes mellitus following prolonged anxiety or sudden shock are recorded to cause these to rank as etiological factors. Many authors have recognized the relation between the gouty diathesis and diabetes mellitus.

It is manifest that glycosuria may be a symptom of many conditions and of diverse lesions. To what number these may in time be limited cannot be premised, but by the studies of von Mering, Minkowski, and Lépine, our knowledge has been much broadened. By careful observation it may be possible in the future to recognize during life various causes for the symptom of saccharine urine, and undoubtedly different plans of treatment will be followed according to the causative condition. M. Lépine has already followed up his experimental work by administering pilocarpine, as a pancreatic stimulant, to a few cases of diabetes mellitus, and, although his cases have been too few to give reliable data, he has had enough success by its use to warrant further investigations in the same line.

CORRESPONDENCE.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

To the Editor of THE MEDICAL NEWS,

SIR: Among almost one thousand guests now enjoying the 2700 feet of elevation and grand outlook of this mountain resort, the fifty members and others present to attend the meeting of the American Ophthalmological Society would attract little attention. At certain times they might be seen conversing in groups on the veranda or in the corridors of the hotel, but during the sessions there are but few absentees, and yesterday they held three sessions. To-day (July 17th) they have completed the consideration of the thirty-five papers brought before them, several of which started animated and prolonged discussions. This afternoon the Society concluded with the consideration of a fine salmon, sent by an absent member, and as his representative most cordially taken in by the Society as a whole, through its individual members.

In executive session, which seems to be guarded by as much secrecy as that of the United States Senate, we learn that three or four new members were elected, and that one name was stricken from the roll.

Of more general interest is the fact that the Society suspended the by-law fixing its time of meeting, and next year will hold its regular meeting in Washington at the time of the meeting of the Second Congress of American Physicians and Surgeons.

It will be remembered that in the year of the first Congress the Society held its regular meeting as usual in July, and a rather small special meeting for the Congress; being then unwilling even for once to give up its midsummer meeting in some cool, quiet summer resort. This time more interest is exhibited in the Congress, and an effort is to be made to secure the presence of prominent European ophthalmologists, and their participation in the meeting.

Of general interest were two cases reported by Dr. William F. Norris, and one by Dr. C. A. Oliver, of brain tumor, recognized and located almost entirely by eye-symptoms, the diagnosis being in each case confirmed by autopsy.

Dr. George C. Harlan reported a transient amblyopia and bitemporal hemianopsia in a case of malarial cachexia, in which, other treatment failing, full doses of quinine quickly brought relief.

Cataract extraction is a subject of perennial interest to the ophthalmic surgeon And an animated discussion was started by a paper on the so-called simple extraction, by Dr. Charles S. Bull, in which he re-affirmed his conviction that it was the best operation for the removal of the opaque lens in a large majority of cases of ordinary senile cataract. This opinion was shared by some of his fellow members, but was not held by quite a number of others.

Much has been said of the advantages of the small, mobile pupil secured by simple extraction. But the small *immovable* pupil, due to iritic adhesions, is of such frequent occurrence as to increase decidedly the risk attending the simple extraction, and to offset its other advantages. It is not claimed to be applicable to all cases; but when successfully performed in a proper case is an almost ideal surgical procedure.

Dr. H. Derby reported a family in which two brothers and a sister and eight out of ten of their children were affected with congenital zonular cataract. There was no history of convulsions in early infancy in any case.

Dr. T. R. Pooley and Dr. R. A. Reeve reported cases of removal of large ivory exostoses from the inner wall of the orbit: and Drs. William F. Norris and L. H. Taylor cases of large foreign bodies lodged for some time in the orbit.

Dr. C. E. Rider, under the head of the "Winking Test," called attention to the strong tendency to wink, or close alone, the abnormal eye, much more readily than the normal, where there was an appreciable difference between the visual acuteness of the two. This he proposed to have used as a test when it was desirable to ascertain which had formerly been the worse eye, as in advanced double cataract, or malingering, or when decided inferiority in the vision of one eye has been recently discovered. The test is, however, scarcely applicable to women, because very many, who have visual acuteness about equal in both eyes, are still unable to wink with either eye separately. No explanation was given of this sexual difference.

Disorders of the ocular muscles were discussed at length in connection with a paper by Dr. H. D. Noyes on the treatment of muscular asthenopia and its results. Graduated tenotomy seemed to be less in favor than in the past two years, and the use of prisms more generally relied on.

A committee on the prevention of blindness found that in this, as in other civilized countries, about 20 per cent. of all blindness is caused by ophthalmia neonatorum.

The general adoption was urged of a law recently enacted in New York, requiring midwives and others to

notify in six hours some health officer, or legalized practitioner of medicine, should inflammation of the eyes of a newborn infant be noticed.

Several speakers testified to the value of the Credé method of dropping into the eyes a 2-per-cent. solution of silver nitrate immediately after birth.

Drs. W. F. Mittendorf and O. F. Wadsworth reported cases of embolism of the central artery of the retina, with the retention of good vision at the macula, by reason of its being supplied by cilio-retinal vessels quite unaffected by the embolism.

Dr. William H. Carmalt reported two cases of sarcoma of the conjunctiva, and two of glioma of the retina. In one of the latter both eyes were removed, and there had been no recurrence. In the other the growth was so soft, and pus-like in consistence, that its nature was not recognized until it recurred, after the enucleation of the affected eye. Death occurred from extension of the growth to the brain.

Cases of remarkably good vision in spite of age and hyperopia were reported by Dr. S. Theobald; and a group of cases of increasing hyperopic astigmatism by Dr. Edward Jackson. These latter cases are rare, but they do occur, and it should be borne in mind that astigmatism sometimes changes.

Dr. Harlan described a new operation for keeping the lid free in symblepharon, by replacing its conjunctival surface by a sliding flap of skin.

Dr. B. A. Randall argued that we have no evidence that hyperopia can be healthfully outgrown; the prevalent idea that it is generally outgrown being quite incorrect and unsupported by facts.

Dr. F. M. Wilson exhibited three specimens of filaria oculi humani, taken from just beneath the skin of the lids of a missionary who had acquired the parasite on the West Coast of Africa. The worm is very frequent on a certain limited portion of the coast. It is most frequently seen just beneath the ocular conjunctiva, and not, as has been asserted, in the anterior chamber of the eye.

Dr. C. W. Kollock reported two cases of a new form of xerosis occurring in colored children, marked by an elevated ring around the margin of the cornea, and quite amenable to general tonic treatment. He also reported two anomalous cases of glaucoma, in one of which the tension quickly rose after an iridectomy, and though unaffected by weak solutions of eserin was promptly reduced by a strong solution. The other occurred in an eye the seat of monocular hæmorrhagic albuminuric neuroretinitis.

The Society, in accordance with its custom, continues in office its officers, viz.: President, Hasket Derby, M.D., of Boston; Vice-president, G. C. Harlan, M.D., of Philadelphia; Secretary and Treasurer, S. B. St. John, M.D., of Hartford.

Hotel Kaaterskill, July 17, 1890.

"THE ETIOLOGY AND TREATMENT OF MIGRAINE."

To the Editor of The Medical News,

Sir: Having been very favorably impressed with the exhaustive and scholarly article by Dr Wharton Sinkler upon "The Etiology and Treatment of Migraine" in The Medical News of July 19th, and believing that, when considered as a disease, too much attention is given to its treatment, I should like permission to offer some suggestions calculated to throw a different light upon the subject, treating it rather as a symptom than as a disease. In the closing paragraph of Dr. Sinkler's paper migraine as a symptom is merely referred to, and, for the most part, the treatment is confined to the exhibition of drugs, or the use of local measures, such as electricity. That my views are entitled to consideration will be apparent from a quotation from the paper, which runs as follows: "Most authors now agree as to the prime importance of hygienic measures in connection with any remedy used for the relief of this disease. Removal from care and work, with fresh air, good food, and change of climate, will do more to relieve the frequency of the attacks than any drug."

Taking this quotation as a text, together with the assumption that migraine is a symptom of disease, the general practitioner will be interested in knowing the methods to be pursued for the purpose of removing the underlying cause of these derangements of the nervous system; and, by way of introduction, I may repeat the time-worn maxim that such attacks are generally due to an impoverished condition of the system, and that neuralgia is the cry of the nerves for pure blood. We not infrequently meet with cases of anæmia with neuralgia, which we have learned to speak of as the anæmia of plethora, and, in these it has been found empirically that purgatives are useful. Still, I doubt if a very large proportion of the physicians who come to this decision and who successfully follow this practice, could give a rational explanation of the *modus operandi* by which the good results are secured. The modern practitioner regards the success of the doctor of a generation ago as somewhat enigmatical, considering the liberal use of purgatives which was the custom of that period; and in calling attention to the treatment of migraine as a symptom of disease, I hope to be able to clear up this matter, so that hereafter purgatives may be used intelligently and in accordance with well-known scientific principles.

The question will be better understood by the presentation of cases in which the cause of the disorder is made apparent, and from which appropriate deductions can be drawn, and the matter settled beyond dispute. For example, does any modern physician doubt the causative relation existing between derangements of the digestive apparatus and attacks of cholera morbus? The disease known as cholera infantum is so closely related to cholera morbus that it ought to be included in the same category, and, without undue stretch of the imagination, the list might be extended by including such specific diseases as typhoid fever, anæmia, and chlorosis, and, in not a few instances, consumption. In regard to the latter disease, I cannot accept the modern theory that the bacillus tuberculosis bears a direct causative relation, but is rather in the nature of an incidental complication. In proof of this assumption, I have but to point to the very large number of persons who suffer for years from what is termed "general debility," but finally the bacilli, finding a suitable nidus for their development, take possession of the tissues. With the rapid multiplication of the germs, and the dis-

tribution of the poisons derived therefrom, the patient begins to sink, and is accordingly treated for pulmonary tuberculosis. No one doubts, now, that many of these patients, if properly treated in time, or, in other words, if those "measures of prime importance" had been adopted, would have recovered, and consumption have been avoided. Without going further into this question, my impression is, that these diseases are, for the most part, due to disorders of digestion, and that by proper attention to diet, including, of course, hygienic measures and climatic treatment, a fatal issue may be indefinitely postponed, if not altogether avoided.

It will be argued that migraine occurs too frequently to be placed in this classification, and that if the proposition is true, other nerves should show derangements of a like character; but upon reflection, and the elimination of those direct causes pointed out by Dr. Sinkler, which may easily be traced, I think the point will be conceded as well taken. In the case of typhoid fever, for example, what observing physician has not witnessed patients who *walked* themselves into the disease? How many patients can the active country practitioner recall, within the period of a year, who have persistently violated his advice and have finally contracted the disease? On the other hand, he is able, at the same time, to point out a number who have carefully complied with his directions and have escaped.

As a rule, it will be found that those who suffer from migraine are under-fed. Notwithstanding that they take a seat at the table three times daily, and apparently enjoy their food, something is wanting either in the primary or secondary assimilation, and this peculiar pain is the result. When there is a rheumatic tendency, it may appear in the form of intercostal neuralgia, or sciatica, or one or more of the joints may be affected. At other times these manifestations will be in the form of fugitive pains, which appear to have no local habitation. The number of persons who suffer from rheumatic tendencies is daily increasing, and it would be difficult to find one of these who does not suffer more or less from indigestion and from acidity of the stomach.

To meet these demands, quite a number of remedies suggest themselves. The most natural conclusion is, that all our troubles will vanish after the introduction of alkalies into the system, but a more specious fallacy was never promulgated, and yet many physicians cling to it with wonderful persistence. Others believe that the difficulty may be overcome by the introduction of acid into the stomach shortly before meals, on the theory that this will lessen the secretion of the acid juice of the normal stomach, and notwithstanding the scientific basis for its employment, the results have been anything but satisfactory. The advocacy of the digestive ferments, together with the temporary benefits which they confer when judiciously used, has furnished employment to hundreds of men, and large manufacturing establishments have sprung up for the exclusive manufacture of these products. Unfortunately, these measures furnish but transient relief. The general use of pancreatic ferments has had a tendency to enable us to locate with more certainty the real causes which combine to produce this abnormal condition, and for this reason I have to suggest that the diet is of the utmost importance.

A few words in relation to the diet will suffice to start the reader in the proper channel of investigation, as it will be impossible in this letter to touch upon the details which naturally present themselves to the thoughtful physician. Attacks of migraine should always be regarded suspiciously, owing to their dependence upon an unhealthy condition of the alimentary tract. While the tongue may offer no indications of mal-assimilation, the history of the onset of the attacks will frequently point to intestinal indigestion, and the most certain method consists in cutting off all foods which have a tendency to cause fermentation after reaching the small intestine. All starchy foods, sweets, and pastry, must be eliminated from the dietary, and the patient compelled to subsist entirely upon properly cooked beef or mutton, to which may be added a little stale bread or toast. When not specially contra-indicated, a little tea, coffee, or cocoa may be permitted with meals. The results of treatment will be manifest in the course of a week or ten days, providing that the patient is not compelled to work too hard, and is placed under favorable hygienic conditions. Without attention to food, clothing, air, and exercise, medication of whatever sort is but palliative.

For the emergency, to relieve the pain and place the patient in a favorable condition, I cannot speak too highly of an assayed preparation of cannabis indica, and in order to present the method of administration in practical form, will record the following illustrative case:

About two months ago, while on professional business in the country, thirty miles from the city, I was compelled to remain during the night, and in the evening was requested to prescribe for a housemaid, aged thirty-five years. This patient had been suffering for nearly three weeks from a most stubborn attack of migraine, which had obstinately resisted the domestic remedies, as well as drugs. The pain was persistent both night and day, and for many nights she had not been able to obtain any rest until four or five o'clock in the morning. The condition of the digestive apparatus was unfavorable, although she had eaten but little food during the time of her illness. There was no history of uterine trouble, and no indications of decayed teeth to account for the persistence of the attack.

At ten o'clock this patient was placed upon the following mixture:

R.—Extract of cannabis indica (Normal Liquid) . . . . . 5 drops.
Water . . . . . 4 ounces.

One teaspoonful was given every ten minutes for one hour. At the expiration of the hour the patient returned to say that she began to feel better after taking the second dose, and that now she felt quite well and perfectly free from pain. As a result, she had a good night's rest, and experienced no symptoms of a return until after sunrise next morning, when there was slight pain on the affected side She was instructed to take one teaspoonful of the mixture at intervals of an hour during the day, and a restricted dietary was ordered. In addition to this treatment, she was advised to take $\frac{1}{100}$ grain of the arsenite of copper after each meal for five days, and it affords me pleasure to add that the patient rapidly recovered, and has had no further symptoms of migraine.

The circumstances connected with this case were somewhat peculiar. She was living in the country,

where the air was especially bracing; her food was well cooked, and she had an abundance of everything that was wholesome; the work was neither hard nor confining, and apparently there was no earthly reason why she should suffer when all the others in the house enjoyed perfect health. Having seen so many cases of this character yield promptly to this treatment, it would be a waste of time to describe others. I should add, in conclusion, that the arsenite of copper was exhibited for its supposed alterative and antiseptic effects, especially where we have to deal with an unhealthy condition of the alimentary canal, a suggestion which will be appreciated by many who have difficulty in getting patients to take drugs with a disagreeable taste. Clinical observation warrants me in saying that it is a remedy of great utility in this class of cases.

John Aulde, M.D.

1910 Arch Street, Philada.

ATLANTA vs. CHATTANOOGA.

To the Editor of The Medical News.

Sir: I have just read Dr. Baird's polite communication in The Medical News of July 5th, under the title of "Typhoid Fever in Chattanooga," and feel constrained to make the following reply:

Notwithstanding Dr. Baird's gratuitous interpretation of the "official records of the Chattanooga Board of Health," and his abiding faith in the old saying that "figures won't lie," the remarkable immunity in this city from enteric or typhoid fever, diphtheria and scarlet fever, is precisely as stated in my paper read before the Association of American Physicians, and published in The Medical News of June 7th.

I submit, in much kindness, that Dr. Baird's own experience as Health Officer of Atlanta should have thoroughly convinced him by this time of the unwelcome truth that the average death-certificate is an unknown quantity, and of all things in this world the most unreliable. Health officers cannot "go behind the returns," no matter how doubtful the correctness of the certificate may be, they must, *nolens volens*, report accordingly.

Dr. Baird has fairly stated that 107 deaths from typhoid fever represent, probably, more than 1000 cases of the disease in any given community where it prevails; yet I doubt if any physician could be found in Chattanooga who would venture the statement that there have been 100 cases of typhoid fever in this city "during the last four years." The occurrence of 50 cases, or less, would have furnished enough *seed*—if the situation were not a sterile soil—to cover the ground, and make the disease so common that there could be no difference of opinion concerning its presence. And is it possible for one to believe that 1000 cases of the disease could have occurred, within four successive years, without attracting the special attention of the local medical profession, and alarming the whole community?

When the population of Chattanooga is alluded to by the Health Department, the thriving suburban communities of East Lake, East End, Ridgedale, St. Elmo, Hill City, Sherman Heights, Highland Park, etc.—aggregating a population of 15,000 or 16,000—are not included. In fact the census just completed show that in the city's limits proper, the population does not exceed 32,500; and it is upon this basis that the Health Department must begin the new decade. The correction as to population makes the "official records" all the more unreliable; for who, indeed, can believe that within the limit of such a population typhoid fever could be so common, yet unknown clinically to such an extent that there are several physicans of large experience in practice in Chattanooga who have not seen a case?

But however disappointing to the pride of enthusiastic Chattanoogans that our boasted "60,000 population," including the suburban centres, has been reduced to less than 50,000, the happy truth remains that the city is remarkable for its almost entire immunity from typhoid fever, diphtheria, and scarlet fever, thus maintaining a most wholesome contrast with all other American cities in public health, and holding, especially, its advantage over Atlanta.

Very soon after my return from the meeting of the Association of American Physicians, the Chattanooga *Daily Times* gave notice of the presence of typhoid fever in some of the outlying districts, with two deaths from the disease; whereupon, at the next meeting of the City Medical Society, I called attention to the newspaper report, and said, if it was true, it flatly contradicted the statement I had made in my paper. In the interest of medical truth, I urged a closer study of the question, if possible, than had hitherto been given it, asserting that it was not complimentary to the medical profession of Chattanooga that there should exist a difference of opinion on the subject. In the same spirit, I addressed the President of the City Board of Health, calling his attention to the newpaper reports above named, and asked for the facts. Here is his reply:

Chattanooga, Tenn., June 12, 1890.

Dr. James E. Reeves, M.D.,

Dear Sir: Your kind note of yesterday received. Allow me to say that the *squib* in the *Times* of yesterday was without my approval, and quite a surprise to me. Since my residence in Chattanooga, I have been very sceptical as to the existence of typhoid fever in the city.

Very respectfully, J. L. Gaston.

The question of the infrequency of typhoid fever in Chattanooga is not a new one, but has, again and again, been discussed in the City Medical Society—called up usually by the report of a "rare case." Within the last few weeks, the "official figures"—for which Dr. Baird has so much respect—barely escaped recording another death from "typhoid fever." The case was, at first, thought to be one of "meningitis;" after a consultation, "typhoid fever." The patient expired suddenly and unexpectedly, and the post-mortem revealed a large hepatic abscess as the cause of death.

The "one physician, in active practice for more than thirty years," who has seen "only three or four cases within that period," is Dr. P. D. Sims, member of the State Board of Health and secretary of the City Board of Health. No one who knows Dr. Sims will doubt his ability to speak positively on this or any other subject connected with medical practice in Chattanooga. His professional standing, large experience in general practice, every quality to make his opinions and utterances command respect, outweigh the "random estimates of

individuals," and sufficiently attest the fact that typhoid fever is but rarely met with in Chattanooga; but why the immunity no physician is wise enough to tell.

Respectfully, James E. Reeves.

201 McCallie Avenue, Chattanooga, Tenn.

NEWS ITEMS.

Orthopædic Surgery at the Berlin Congress.—Dr. Newton M. Shaffer, Chairman of the Orthopædic Section of the New York Academy of Medicine, announces that a Section of Orthopædic Surgery has been formed by the Committee of Organization of the approaching Berlin Congress. Members of the profession interested in this department of surgery are requested to be present at the Congress and to become members of the Section.

Medico-legal Society of Chicago.—At the annual meeting of the Medico-legal Society of Chicago, held June 7, 1890, the following officers were selected for the ensuing year: *President*, Dr. E. J. Doering; *Vice-Presidents*, Dr. B. Bettman and Judge O. H. Horton; *Treasurer*, Dr. L. L. McArthur; *Secretary*, Dr. Edward B. Weston.

Case of Beri-beri.—A case of beri-beri has recently been received at the Long Island College Hospital, to which institution it was removed from the Quarantine of New York Harbor. The disease is a very unusual one here, and this case presents itself in the person of a sailor on the German ship "Warns."

Burial Reform in London.—The dangerous overcrowding of the London cemeteries has been often commented on by the medical press of that city, but the evil remains almost wholly unabated. The Sanitary Committee of the London County Council has reported that no time should be lost in closing burial grounds such as the Brompton, which contains 155,000 bodies; and the Tower Hamlets Cemetery, with its 247,000 bodies crowded into only seventeen acres. The average grave is seven by three feet, and contains eight adults and fourteen children, the covering of earth being about one foot. In one instance, a committee of inquiry regarding this cemetery found eighty infants interred in a grave or trench of less dimensions than that of the average grave. There are twenty-one burial places, with a total extent of less than 300 acres, holding a million and a quarter of bodies. The soil in most of these places is clay, and the process of decomposition goes on so slowly that bodies buried for a dozen years remain remarkably well preserved. This unfortunate state of affairs, especially as seen in the overcrowding that takes place wherever the bodies of the poor are buried, is universally acknowledged to be a serious menace to the public health and to demand the prompt attention of the government.

The Antisepsis of Oath Administration.—The *British Medical Journal* states, under the title of "Kissing the Book," that the old-fashioned greasy book so often tendered in the law courts to a witness about to be sworn, is a source of danger that is fully recognized by some officials. For example, when the Duke of Fife appeared lately at Stratford in a prosecution, the book on which he took the oath was enveloped in a piece of clean, white paper for his use, a precaution that might with advantage be more generally adopted. The *British Medical Journal* proceeds to ask, "Why should not the formula of the oath taken in our courts of justice be altered—possibly in imitation of the method in vogue in Scotland, which is that of raising the hand—in lieu of kissing the book?" Not long since a woman was a witness in a court in Philadelphia, and when taking the stand to testify refrained from kissing the dirty volume presented to her by the court officer, whereupon a juror objected to her testimony because, as he said, it was invalid and incomplete by reason of her omission of this time-honored ceremonial; but the judge ruled that an oath was valid without the kissing of the sacred volume, and that the kissing itself was a relic of idolatry that should be abolished. "I think," he said, "that this witness has refrained from kissing the book, not because she has any intention of giving false testimony, but because it is a dirty book. I respect her regard for her person and her health."

In almost every civilized country, people who have scruples against swearing are relieved from that formula by the simpler "affirmation" to the truth of their proposed testimony. Affirmation may be less impressive to certain classes, but it commends itself as a clean and safe method.

Antivivisection Bitterness.—The Society for the Protection of Animals from Vivisection recently held its annual Spring conference in London. The war-cry this year was "Pasteurism and Crime," and Canon Wilberforce is reported to have rejoiced in the fact that the movement to found a Pasteur Institute in England had been defeated by the society's method of placarding the city with large posters, containing the list of those who had died after treatment by the Pasteurian system. Many others indulged in bitter denunciation of both vivisection and Pasteurism, as being the means of brutalizing the otherwise honorable and useful profession of medicine. One speaker likened vivisection to the liquor traffic, and said that inasmuch as it would be impossible to regulate either by laws, they must be torn out root and branch. Other speakers said that they could prove by competent medical testimony that humanity had been injured by the attempt to apply the results of investigations made on the inferior animals. Altogether, much zeal, though but little knowledge, was exhibited by these people, who are friends to every animal but man.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, AUGUST 9, 1890. NO. 6.

ORIGINAL ADDRESSES.

ANÆSTHESIA.

An Address delivered before the International Medical Congress, Berlin, August 6, 1890.

BY H. C. WOOD, M.D., LL.D.,
PROFESSOR OF THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

THE most brilliant modern achievements, in the direct saving of life, of the science and art of medicine are connected with surgery. These great achievements have been rendered possible by two epoch-making discoveries, antisepsis and anæsthesia. The long array of fatal cases of poisoning by carbolic acid, by iodoform, by corrosive sublimate, and by other antiseptic agents; the hundreds of deaths from chloroform, ether, and other anæsthetics, all bear witness to the verity of that strange law, in obedience to which the progress of the human race is so often at the sacrifice of the individual. Antisepsis has outgrown the dangers of its youth, and to-day the measures that are meant to save, very rarely kill. On the other hand, the death-roll of anæsthesia is daily added to; added to, according to my belief, at a rate that has not changed in forty years. Though this be true, from far-off Australia comes the news that jury and judge have condemned to heavy penalty a chloroformist who had lost his patient; and in Old England itself, the leading medical journal lends support to such a verdict by affirming that "deaths from chloroform are preventable, that with due care they may be avoided," and that, therefore, when they occur, they are the result of ignorance or carelessness. Five hundred deaths and more—the result of ignorance or carelessness! Five hundred surgeons, including such names as Billroth, Jaeger, Simpson, McLeod, Agnew, Hunter McGuire, and others of equal rank, guilty of manslaughter! And still the carnage goes on. Surely under such circumstances the subject of anæsthesia is worthy of the attention of even this, the most learned medical gathering of the nations that the world can furnish. Antisepsis, the gift of the Old World to humanity: anæsthesia, the gift of the New World, which made the fruits of antisepsis possible: surely it is fitting that I, standing here to-day before you all, as the representative of the newer civilization, should be the chosen mouthpiece for the renewed discussion of this old but pressing theme.

In attempting a fresh study of a well-threshed-out subject, I propose to take advantage of the modern physiological methods, and to endeavor to discover by experiments upon the lower animals how anæsthetics kill, and what drugs or measures are most powerful in putting aside their lethal effects. This brings us face to face with the question—How far is it possible to adapt experiments to the needs of practical medicine, and to reason from the dog to the man? A full discussion of this subject would not be opportune, but it does seem necessary for our purpose to devote a few minutes to the pointing out of certain general guiding principles.

It ought to be acknowledged as a fundamental axiom, that no amount of experiments can overthrow a clinical fact; although when a contradiction between experimental and bedside observation seems to arise, such contradiction challenges the correctness of the alleged clinical and experimental facts alike, and should lead to a careful reëxamination. No amount of failure to purge a dog by elaterium proves that elaterium does not purge man; whilst, on the other hand, the discovery that digitalis increased the blood-pressure in the lower animal very properly led to doubt as to the correctness of the, at the time, general belief that digitalis acts upon man as a cardiac sedative, and finally to the recognition of the falsity of the clinical observation upon which such belief rested.

Whatever difficulties may beset the path of the experimental therapeutist, it is certain that law is throughout the universe supreme: that man, at least in his physical nature, is only an especially developed animal: and if drugs act differently upon different animals, such action must be in obedience to certain laws, to us known or unknown.

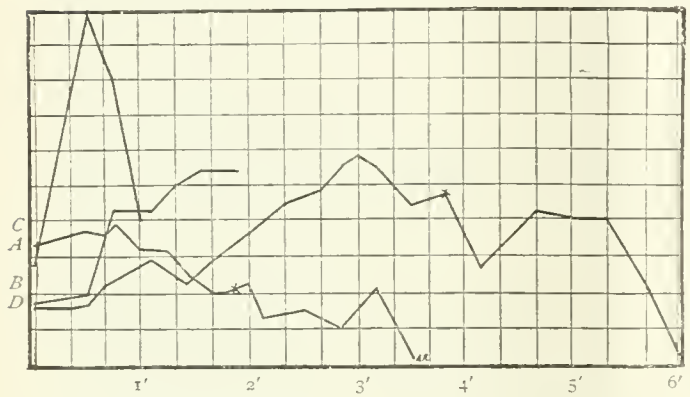
Any attempt to discuss fairly these laws would lead us too far afield for the present. One law, however, treads so closely upon the matter at hand this morning, that it requires statement. This law is, that when an apparatus or system is of similar function and of similar functional activity in different animals, the difference in the action of remedies is very rarely, if ever, in kind, though it may be in degree. Throughout mammalia the heart has one general structure, and one general function; the heart of the dog responds to the touch of digitalis precisely as does the heart of the man. The human brain is so much more highly developed than the brain of the lower mammal, that it is, in fact, a new organ or apparatus, and its relation to drugs changes with the change of structure and of function. The scope of this law in regard to anæsthesia is not far to seek. The functions especially compromitted in lethal anæsthesia are respiration and circulation. Surely these functions are similar throughout mammalia, and surely we ought to be able to reason safely concerning them, from the dog to the man.

Recently, however, alleged clinical facts have been challenged by high authority, upon the strength of experimental results. Under these circumstances, nothing must be at once abandoned, everything must be reexamined. These reëxaminations I have made, and I may be pardoned, perhaps, if I affirm that a complete study of the clinical and experimental evidence brings out, not a discord, but a most beautiful concord—that concord between experimental and practical medicine which so often fails to appear simply because we cannot fit together the fragments of truth in our possession.

Although numerous substances have been tried, there are to-day in use, practically, only three anæsthetics—nitrous oxide, ether, and chloroform. Of these, nitrous oxide stands apart, because it produces loss of consciousness not by virtue of any inherent properties, but simply by shutting off from the nerve-centres the supply of oxygen.

It has been asserted that the changes of circulation produced by the inhalation of nitrous oxide are essentially different from those of mechanical asphyxia, and that therefore nitrous oxide does not act as an asphyxiant. It must, however, be borne in mind that the phenomena of mechanical asphyxia are largely due to the presence of an excess of carbonic acid in the blood, whilst in the asphyxia produced by nitrous oxide there is no excess of carbonic acid, so that the phenomena present are simply the outcome of a lack of oxygen. It is, therefore, *a priori*, to be expected that the phenomena of mechanical and of nitrous oxide asphyxia should differ to a certain extent. To determine the way in

FIG. 1.



Plot showing effects of inhalation of nitrous oxide upon blood-pressure. *A*, first inhalation. *B*, second inhalation. *C* and *D*, inhalations in different dogs.

which nitrous oxide inhalation affects the circulation, I have, during the past winter, in connection with my assistant and friend, Dr. David Cerna, made a long series of experiments. The result has been to show that usually the inhalation is followed by a rise of the arterial pressure, accompanied by a great disturbance of the pulse; the pulse at first becoming irregular and tumultuous, but by and by settling, so that when anæsthesia is complete the pulse-wave is remarkably large and full, and the rate very slow. The rise and fall of the arterial pressure in nitrous oxide anæsthesia was found to vary remarkably, not only in different inhalations, but in different periods of the same inhalation. Sometimes the rise was sudden, sometimes it was slow and gradual: sometimes it was maintained until near death, sometimes it was interrupted very early: sometimes it was not very well marked, sometimes it was enormous. As illustrating it, I have the accompanying diagrams, accurately showing the curve of the blood-pressure obtained in four inhalations practised on three different dogs. (Fig. 1.)

In all our experiments respiration ceased while the heart was still in full activity. Indeed, instead of the gas acting as a cardiac depressant, it appeared to act as a cardiac stimulant, although it paralyzed the vaso-motor apparatus. Thus, during complete anæsthesia, faradic irritation of the sciatic nerve always failed to register itself in an increase of the blood-pressure, although the heart was beating very powerfully, and although the pneumogastrics had been previously severed: whilst late in the poisoning—at a time when the respiration had absolutely ceased, and the animal was in this respect dead, and without the power of self-recovery, and when the arterial pressure also had fallen almost to zero—the pulse-waves were frequently still nearly three times the norm. In evidence of this I append a reproduction of a tracing (Fig. 2).

We made but few experiments as to the action of artificial respiration upon the animal dying from nitrous oxide, but these experiments proved that even after complete paralysis of the respiratory function, artificial respiration is capable of rapidly bringing the animal

Figure showing the relative size of the pulse waves in nitrous oxide anæsthesia. Tracing *A*, before inhalation. Tracing *B*, after breathing had stopped.

back to life. The heart lives on through nitrous oxide anæsthesia long after the respiratory function has been abolished, and even when the strong, full pulse fails, and the heart has almost ceased to quiver, recovery is still hopeful, because the loss of function has been caused, not by the presence of a poison, but by the absence of oxygen; and although the paralysis may be complete, the life-power sleeps before it dies, and is ready to awake at the touch of fresh oxygen.

These experimental results are in strict accord with clinical observations. The S. S. White Dental Manufacturing Company supply a very large, if not the largest, portion of the apparatus and material used for the administration of nitrous oxide in the United States; and, in answer to my inquiry, Dr. J. W. White, their President, writes me that a computation based upon their own sales, and a knowledge of those of their rivals, has reached "the somewhat appalling result, that anæsthesia by nitrous oxide gas is probably effected in three-quarters of a million of cases annually in the United States." Most of these inhalations have been given, not by trained physicians, but by comparatively untrained, and often

very ignorant dentists; have been given to patients in a sitting or semi-sitting posture: have been given apparently without thought or care to the general community, as the units presented themselves, to the healthy and to the diseased alike; and the result is, out of many millions of inhalations only three deaths recorded as directly due to nitrous oxide! Could anything be safer?

A suggestive and very practical fact which came out in our experiments, is that sometimes during an inhalation of nitrous oxide the rise of the arterial pressure is extraordinary and abrupt. Not long since, in the city of Philadelphia, a gentleman arose from the dentist's chair after an inhalation of nitrous oxide, staggered, and fell in an apoplexy. Is it not easy to perceive that when the arterial system is diseased, the great strain of a sudden rise of blood-pressure may produce rupture?

Some years since, Dr. Kenderdine, a Philadelphia surgeon of local note, died of diabetes, which he insisted was produced in him by the inhalation of nitrous oxide. This is in accord with the researches of the French physician Dr. Lafont, who reported a case in which sugar appeared in the urine twice in a patient, after inhalation of the gas; and who also caused in himself, and in dogs, temporary glycosuria by such inhalations. Further, Dr. Lafont noticed in a case of mitral insufficiency temporary albuminuria.

I am not aware that these very suggestive statements of the French physician have given rise to any research, except five experiments made recently upon healthy men, with negative results, by two medical students of the University of Pennsylvania, Messrs. George S. Woodward and Alfred Hand, Jr. I do not believe that ordinarily the inhalation of nitrous oxide is followed by sufficient disturbance of the circulation to register itself in the urine, but the negative evidence of Messrs. Woodward and Hand is not sufficient to render it improbable that in exceptional cases the inhalation of nitrous oxide may produce albuminuria or glycosuria. Such phenomena, if they occur, are in all probability not directly produced by the nitrous oxide, but are due to the disturbances of capillary circulation caused by it.

However these facts may be, it seems to me that great caution should be used in the administration of nitrous oxide to persons the coating of whose arteries is diseased, and it is probable that when widespread atheroma exists, ether is a safer anæsthetic than nitrous oxide.

When respiration has been suspended in nitrous oxide anæsthesia the overwhelming indication is certainly for the employment of artificial respiration.

Notwithstanding the great safety and the many advantages which attend the anæsthetic employment of nitrous oxide, the gas can never be used for the general purposes of the surgeon, on account of the excessive fugaciousness of its influence.

The perfect anæsthetic will be a substance which has the power of paralyzing the sensory nerve-trunks without affecting other functions of the body. If such drug exists, it yet awaits the coming of its discoverer. Probably until such a sensory nerve paralyzant is found, chloroform and ether will maintain the complete supremacy which they now have; and in the further discussion of my subject I shall confine my remarks to them. Lack of time limits this discussion to:

First. The method in which these two drugs kill, both in man and in the lower animal; that is, whether they destroy life through the circulation or the respiration.

Second. The comparative fatality attending the use of these two agents, and the reasons for the difference.

Third. The comparative disadvantages between the two agents, and the best method of securing the desired results.

Fourth. The treatment of accidents occurring during ether or chloroform anæsthesia.

In regard to the method in which anæsthetics kill, my own teaching hitherto has been: first, that although ether in moderate doses acts as a stimulant to the circulation, yet in overwhelming amount it is capable of depressing the heart, but that such depression of the heart is always less than the depression of the respiration, and therefore, ether kills always through the respiration; second, that chloroform may produce death by paralysis of the respiratory centre, or by a simultaneous arrest of respiration and circulation, but that primary paralysis of the heart may occur, and is especially prone to do so when the chloroform vapor has been given in concentrated form.

I think that these views are in accord with general professional belief, but it has recently been alleged that they are at variance with experimental evidences, so that a reëxamination is necessary. What then are the clinical facts?

If any credence is to be attached to the statements of competent witnesses, who have recorded human deaths during anæsthesia, it is certain that in some cases, under the influence of chloroform, the pulse and respiration have ceased simultaneously; whilst in other instances the respiration has failed before the pulse; and in still other cases the pulse has ceased its beat before the respiratory movements were arrested.

Usually ether arrests respiration in man before it paralyzes the heart, but the collection of records made by Dr. J. C. Reeves certainly shows that the fatal result may be produced by syncope. Thus Dr. Ernest H. Jacobs, in a report of a fatal case, asserts positively "the pulse ceased, the breathing continued." It would seem that we must admit that ether in the human subject may cause death in the same methods as does chloroform.

Such then are the clinical facts; or in other words, such are the results of observations made upon the human subject. What are the results of observations made upon animals?

The general teaching in regard to chloroform has been recently challenged by Dr. Lauder Brunton, who, as the result of 450 experiments made by himself upon the pariah dogs of India, has reached the conclusion, published in the London *Lancet*, that however concentrated the chloroform may be it never causes death from sudden stoppage of the heart. In the physiological laboratories of the University of Pennsylvania, for some years, several hundred dogs have been annually used, and a very large proportion of these dogs have been, at the end of an experiment, killed by chloroform. The observations of Dr. Reichert, Professor of Physiology in the University, Dr. H. A. Hare, Demonstrator of Therapeutics, and myself, have been concordant in showing that chloroform is a cardiac paralyzant, and often does kill dogs by a direct action upon the heart or its contained ganglia. The statements made con-

cerning the Hyderabad Commission, however, led Dr. Hare and myself to a thorough and careful restudy of the subject. Some of our experiments were made by injecting chloroform into the jugular vein; others by administering it by inhalation in the usual way.

The action of the chloroform seems to be not seriously modified by the method of administration. We definitely proved that in the dog chloroform has a distinct, direct, paralyzing influence on both respiration and circulation; that the respiration may cease before the heart-beat, or the two functions be simultaneously abolished; but that in some cases the heart is arrested before respiration. We have several times seen the respiration continue as long as one, and even two minutes after the blood-pressure has fallen to zero, and the pulse has completely disappeared from the carotid artery.[1]

The correctness of our experiments, we claim, must be acknowledged. The experiments have not only been witnessed by a number of persons, but I have with me to-day tracings which I will gladly show anyone especially interested in the subject. I do not desire to express any doubt whatever as to the correctness of the experimental data of Dr. Brunton; I simply claim that both sets of experiments, although they have yielded different results, have been correctly and properly performed. It may be that the high heat or other climatic conditions surrounding the pariah dog make his heart less sensitive to the action of chloroform than is the heart of the dog bred in Northern climates. That the thought of the different constitutions of animals in different climates is not absurd, is shown by the fact that some years ago, after I had affirmed before the Physiological Section of the International Medical Congress at London, that if certain asserted results were obtained upon European dogs, said dogs must differ from those of America, and had been met with a smile of incredulity, Dr. Brown-Séquard rose and stated that he had experimented upon hundreds of dogs on both continents, and that there was a distinct difference between the animals, the vascular system of the European dogs being much more developed, and operations upon them being, therefore, much more bloody than was the case with the American dog.

A very curious parallel might be traced at this point between the experimental and clinical evidence in regard to the effect of climate upon the action of chloroform. In the Southern United States chloroform is used with great freedom, and with great alleged safety; and as long ago as 1878, Dr. Landon B. Edwards, editor of the *Virginia Medical Monthly*, wrote: "It is one of the most peculiar facts I have ever known in medical practice—the difference of experience in Europe and the North, with chloroform and ether, as compared with that of the South—the high rate of mortality in the North, and the low rate in the South.

In a series of experiments which I have recently made to determine the changes in the circulation produced when ether anæsthesia is carried on to death, I have found that in the first periods of anæsthesia the blood-pressure is usually elevated, and that it is usually quite high at a time when the respirations are very shallow and imperfect, and the dark color of the blood shows that it is heavily charged with carbonic acid. It is not, however, very rare for the blood-pressure to remain near the norm, and I have seen the blood-pressure begin to fall in the very first stages of ether anæsthesia; moreover, in at least two experiments death occurred from syncope, the respiration continuing for one or two minutes after the complete cessation of the circulation. In an experiment in which the fall of blood-pressure was most pronounced, and the arrest of the heart most complete, the dog was sick from the mange, and it is possible that the weakened heart was more susceptible than is the normal heart to the depressing influence of ether.

FIG. 3.

Tracing showing respiratory movements, *B*, registered one and a quarter minutes after circulation had fallen as shown in *A* during death from ether in the dog.

So far, then, as concerns the method in which ether and chloroform kill, I claim most urgently that there is no contradiction between the results as obtained by the bedside and in the physiological laboratories, and that a complete, broad study of the clinical and experimental evidence leads to one conclusion, namely, that chloroform and ether are capable of paralyzing the respiration and the circulation; that in some cases one function, in other cases the other function, is primarily arrested; but that ether is less prone to produce a primary arrest of the heart than is chloroform.

In the discussion of the second point which I have raised, namely, the comparative fatality attending the use of ether and chloroform, I shall not occupy time with any elaborate setting-forth of the clinical evidence. In regard to the number of recorded deaths, I shall content myself with accepting the latest statistics at hand, namely, those collected by Dr. Laurence Turnbull, who has found 375 deaths reported from chloroform, and 52 from ether. I do not believe that these figures nearly represent the total mortality; I doubt very much whether one-third of the deaths from anæsthesia are reported; certainly not one-third of the cases I have had personal knowledge of have been publicly recorded. Moreover, the pressure to conceal deaths from chloroform is greater than when the lethal result is due to ether. The surgeon who uses ether feels that he has employed the safest anæsthetic, and that he will receive no blame if a death occurs from it, and feels also that he has a rare case to put on record, which will give his own name a permanent place in anæsthetic literature; whereas the surgeon who uses chloroform knows that if death occurs from the anæsthetic, a very large proportion of the profession, at least in the United States, will condemn him either in public or secret for the use of this drug, and that he will be fortunate if he escape being publicly condemned by a coroner's jury. Moreover, deaths from chloroform are only too common, so that the surgeon has nothing to gain and much to lose by publication of a chloroform death, and if possessed of the average human nature, holds his peace. The Coroner's Physician of Philadelphia, Dr. Formad, informs me that he has made autopsies in 15 cases of

[1] No tracings showing these facts are here given because they have been previously published in THE MEDICAL NEWS (February 22, 1890).

ether death, only 3 of which have been reported in medical journals: how many chloroform deaths have been lost in eternal quiet?

It seems to me impossible to get at the exact number of anæsthetic deaths, or the proportionate fatality of ether and chloroform. Lyman considers that in regard to chloroform, the ratio of deaths to inhalations is 1 in 5860; Richardson, that it is 1 in 2500 to 3000. Andrews puts it for ether, at 1 in 23,204; and Lyman, at 1 in 16,542.

Without claiming strict accuracy for any of these figures, I think it can be asserted that the ratio of deaths from chloroform is probably at least four or five times that of deaths from ether.

When we come to study the effects of chloroform upon the lower animals, we find that it varies very distinctly in its action on the different species. The cat seems to withstand the fatal influences of chloroform with a power worthy of its reputed "nine lives." Many years ago, Professor Schiff called attention to the fact that the use of chloroform as an anæsthetic in the dog is usually attended with the loss of many animals. Professor Martin, of the Johns Hopkins University, writes me that the margin between complete chloroform anæsthesia in the dog, and chloroform death, is a very narrow one. This certainly is our experience in the University of Pennsylvania; we have never been able to use chloroform as an anæsthetic without losing a very large proportion of our dogs.

Clinical and experimental results—*i. e.*, the results of experiments made in the physiological laboratory upon the lower animal, and the results of experiments made in the amphitheatre upon the higher animal, Man—are again concordant. Chloroform is much more inimical than ether to animal life. The cause of this singular fatality is not, however, chiefly the cardiac action of chloroform. Chloroform is more apt to cause cardiac arrest than is ether, but it is also much more prone than is ether to cause death by failure of the respiration. Almost invariably, when ether is withdrawn before the dog is absolutely in the grasp of death, recovery occurs; but over and over again I have noticed that although the chloroform was taken away whilst the respirations were still being maintained with regularity, the arterial pressure much above zero, and the pulse very apparent, yet the symptoms of cardiac and respiratory failure continued to increase until the fatal issue was reached.

It seems to me that certain general facts or principles in regard to anæsthesia must be considered as established:

First, that the use of any anæsthetic is attended with an appreciable risk, and that no care will prevent an occasional loss of life.

Second, that chloroform acts much more promptly and much more powerfully than ether, both upon the respiratory centres and the heart.

Third, that the action of chloroform is much more persistent and permanent than is that of ether.

Fourth, that chloroform is capable of causing death either by primarily arresting the respiration, or by primarily stopping the heart, but that commonly both respiratory and cardiac functions are abolished at or about the same time.

Fifth, that ether usually acts very much more powerfully upon the respiration than upon the circulation, but that occasionally, and especially when the heart is feeble, ether is capable of acting as a cardiac paralyzant, and may produce death by cardiac arrest at a time when the respirations are fully maintained.

Chloroform kills, as near as can be made out, proportionately four or five times as frequently as does ether; partly, no doubt, because it is more powerful in depressing the heart, but largely because it lets go its hold much less rapidly than does ether when inhalation ceases. Is it not possible that this "holding on" is because it is less volatile than ether, and can we not here get a hint why chloroform is less deadly in the South than in the North? The diffusibility of vapors or gases is in inverse proportion to the square of their densities, and the vapor of chloroform would certainly diffuse itself with far greater rapidity at 90° F. than at 70° F.

The comparative advantages and disadvantages of the two anæsthetics in practical medicine, are so well known, that only one or two points seem to force themselves upon our present attention. I cannot see that the surgeon is justified in putting the life of the patient to the unnecessary risks of chloroformization, except under special circumstances. I believe, moreover, that much of the unpopularity of ether is due to its improper administration. It is so easy to embarrass the respiration seriously by the folded towel, as commonly used, that not only are the struggles of mechanical asphyxia almost invariably produced, but probably death itself is sometimes caused. Especially is there danger of death being thus caused mechanically in the advanced stages of etherization, when the patient is too thoroughly etherized to struggle, and when the attention of the etherizer is, it may be, attracted by some novel and difficult operation. I myself confess to having once nearly killed a patient in this way.

A proper apparatus is certainly preferable to the folded towel. Various apparatus have been invented, but as the time is short I shall only mention one—one which seems to me a practically perfect mechanism, although it is probably little known this side of the Atlantic.

The inhaler invented by Dr. O. H. Allis is based upon the theory that the patient to be etherized should be supplied with a full abundance of air, saturated with the vapor of ether. It consists essentially of a series of foldings of muslin on a wire framework, arranged almost like the gills of a fish, so as to allow the air to pass freely through, but everywhere to come in contact with ether. It should be placed upon the face of the patient dry, and the ether gradually poured on from a bottle with an especially prepared cork, known in Philadelphia as the "polyclinic" bottle. When properly used the Allis inhaler practically does away with the sense of suffocation, and the consequent struggles which have made etherization alike so repulsive to patient and surgeon.

In order to determine the rapidity with which etherization can be produced by this inhaler, Dr. M. H. Williams kept for me notes of thirteen consecutive cases in the clinic of the Jefferson Medical College Hospital in Philadelphia. The average time required for the production of complete unconsciousness was eight minutes. The average time during which anæsthesia was fully maintained was thirty-two minutes; and the average amount of ether used during this time was 7½ ounces. In 21 surgical cases occurring this spring in the clinical

service of Professor J. William White, of the University of Pennsylvania, the average time for the production of complete anæsthesia with ether, used through Allis's inhaler, was seven and nine-tenths minutes. The results arrived at in these two clinics are so close that eight minutes must be considered the average time required for full etherization by this apparatus.

In discussing the treatment of the accidents of anæsthesia, the results obtained at the bedside naturally press forward for careful consideration, but in going over the subject from this point of view, I have found so little that was novel, and so little that was satisfactory to myself, that I shall not occupy the time of this Congress with any conclusions drawn from reported cases, or personal experience in chloroform accidents. I do not think myself that the problem can be solved by any such study of cases. Death is so near and so terrible, time is so absolute, moments so important, that no surgeon would be willing or justified in waiting for the effect of any one remedy; and when a man is dosed with alcohol, nitrite of amyl, hypodermic injections of ether, digitalis, atropine, and other powerful agents; faradized, slapped, douched, stood on his head, subjected to chest movements for artificial respiration, and to various other measures too numerous to mention; who can tell, if by chance he recover, why he has done so? or who can point out, if by chance he die, what is the remedy whose omission or commission has led to the fatal result?

The problem is a very complex one, not to be worked out amidst the excitement and responsibilities of the amphitheatre. Only in the physiological laboratory can its various elements be separated and studied each by itself, without regard to the individual life which is at stake.

In the physiological laboratory two distinct paths open, each promising to lead to some positive knowledge. We may, on one hand, enter upon the study of the minimum fatal dose of the anæsthetic, and of the results by the concurrent or subsequent administration of its supposed physiological antagonist; or we may investigate the effect of remedies upon functions that are failing under the influences of the anæsthetic.

The objections to the first of these methods have been, in the present instance, overwhelming. The accidents seem to be independent of the amount of anæsthetic inhaled; and such a method of investigation would have required far more time than was available after I had had the honor of being asked to address this body. Death is produced by chloroform and ether through paralysis of the respiration and the heart, and the method of experimental study which I have employed consisted in a study of the action of powerful agents upon these functions when oppressed by chloroform. I have selected chloroform chiefly because it is the more powerful agent of the two anæsthetics, and the more certain in its lethal results.

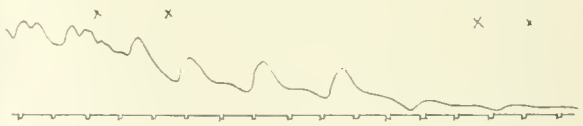
The experiments have all been made upon dogs, by one plan. The carotid artery and also the trachea, having been connected with a recording drum, so that the movements of the circulation and the respiration could be consecutively recorded, the animal was anæsthetized, and when the blood-pressure had fallen almost to zero, and the respiration had ceased, or nearly ceased, as the case might be, the remedy to be tried was injected into the jugular vein, through a canula which had been previously inserted.

The more important remedies which have been used by clinicians for the averting of threatened death during anæsthesia are ether, alcohol, ammonia, nitrite of amyl, digitalis, atropine, and caffeine, alterations of position, and artificial respiration.

Although, at least in America, hypodermic injections of ether have been frequently employed even in ether accidents, such use is so absolutely absurd that it does not seem to me to require any experimental evidence of its futility. Ether in the blood acts as ether, whether it finds entrance through the lungs, through the rectum, or through the cellular tissue; and the man who would inject ether hypodermically into a patient who is dying from ether, should, to be logical, also saturate a sponge with the ether and crowd it upon his unfortunate victim.

Instead of simply stating the results obtained in my experiments, I have thought it would be more interesting to show reproductions from some of my tracings. The first drug that I shall report upon is caffeine. I have injected it during the cardiac failure produced by chloroform, in doses varying from 3 to 7½ grains, and have never been able to perceive any distinct alteration in the arterial pressure, and no consistent distinct change of the pulse either in number or force. So far as the experiments go, they certainly indicate that the drug has no influence upon the heart that is being overpowered by chloroform. I may also state here, that it is not possible in any of my tracings to make out any influence exerted by caffeine upon the respiration.

FIG. 4.



Anæsthesia complete. Dog still breathing. ½ gramme of caffeine injected at X X, each.

With atropine, I have made a few experiments, the results being almost as negative as with caffeine. Ten c.c. of a 2-per-cent. solution of atropine injected into the jugular vein of a chloroformed animal, altered the rate of the pulse-beat, but had no apparent effect or influence upon the arterial pressure, or upon the respiration, and in no wise prevented final cardiac arrest.

Of all drugs, that which I think is usually most relied upon by clinicians as a cardiac stimulant in anæsthesia, as in other cases of heart-failure, is alcohol. The chemical and physiological relations of alcohol to ether and chloroform are, however, so close, that many years ago I became very doubtful of the value of this drug as a stimulant to a heart depressed by anæsthesia.

These doubts continually grew stronger from what I saw and read as to the effects of the administration of alcohol during anæsthesia, and were finally changed into conviction by the experiments of R. Dubois (*Progrès Médical*, 1883, xi. 951), who found that in the animal to which alcohol has been freely given, much less chloroform is required than in the normal animal, to anæsthetize or to kill; or in other words, that alcohol

intensifies the influence of chloroform and lessens the fatal dose.

In my own experiments with alcohol an 80-per-cent. fluid was used, diluted with water. The amount injected into the jugular vein varied in the different experiments from 5 to 20 c. c.; and in no case have I been able to detect any increase in the size of the pulse, or in the arterial pressure, produced by alcohol, when the heart was failing during advanced chloroform anæsthesia. On the other hand, on several occasions, the larger amounts of alcohol apparently greatly increased the rapidity of the fall of the arterial pressure, and aided materially in extinguishing the pulse-rate.

Fig. 5.

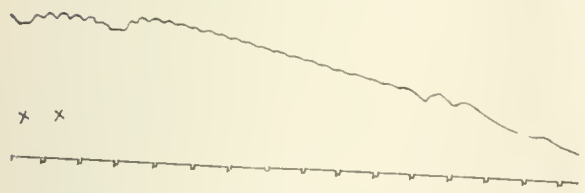
No. 2. five cubic centimetres of 80 per cent. at X.

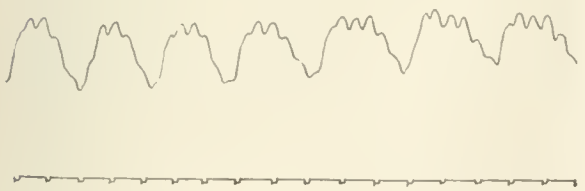
Fig. 6.



Experiment showing effect of injecting twenty cubic centimetres of alcohol in advanced chloroform anæsthesia. Injection made at beginning of tracing between X and X.

The effects of ammonia upon the failing heart of chloroform anæsthesia, has been in my experiments uncertain; sometimes distinct, although very fugacious,

Fig. 7.



Injection of twenty cubic centimetres of a 10-per-cent. solution of aqua ammoniæ fortior. Injection given just after beginning of tracing.

and sometimes imperceptible. Twenty cubic centimetres of a 10-per-cent. solution of aqua ammoniæ fortior (U. S. Pharmacopœia), in some cases produced an immediate rise in the arterial pressure, and even fugaciously registered itself in the respiratory rate, but perhaps more frequently it failed in its influence.

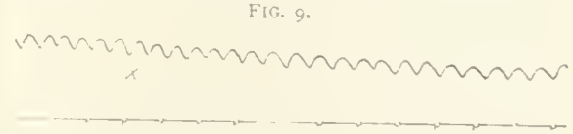
The influence of injections of digitalis has been, in a number of experiments, very pronounced in producing a persistent gradual rise of the arterial pressure with an increase in the size of the individual pulse-rate. In several instances, death was apparently averted by its injection, and I saw in one or two cases, where large amounts of the digitalis had been employed, sudden systolic cardiac arrest, indicating that digitalis, if in sufficient amount, is able to assert itself victoriously in opposition to chloroform. Moreover, when I have given chloroform to dogs whose hearts were already under the influence of digitalis, there has seemed to be a peculiar steadying or sustaining power combating the circulatory depression naturally produced by the anæsthetic, and I believe that in all cases of weak heart in man a full dose of digitalis before the administration of chloroform would greatly lessen the danger of cardiac collapse.

Fig. 8.

Tracing showing effect of five cubic centimetres of tincture of digitalis in advanced chloroform anæsthesia. Injection given at X.

With the nitrite of amyl four experiments were made; in some of these from 4 to 10 drops of the nitrite of amyl were injected in the jugular vein; in others the nitrite was used by inhalation. No distinct effect upon the arterial pressure was in any instance produced, and usually no alteration in the size of the pulse-waves, although sometimes the pulse did appear to be a little fuller.

Fig. 9.



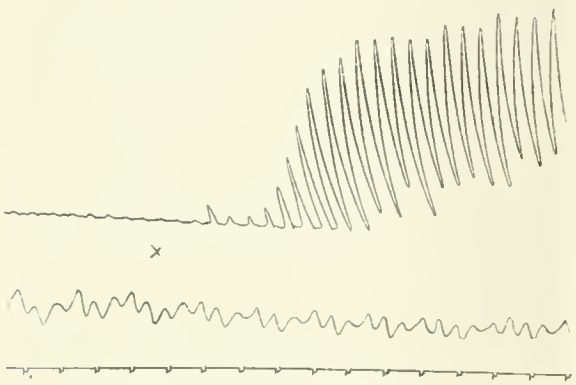
Tracing showing effect of nitrite of amyl, given freely by inhalation, upon the circulation. Inhalation begun at X.

Of all my experimental results, those which have been reached with strychnine have been the most surprising. The injection of strychnine into the jugular vein usually produced a gradual rise of the arterial pressure, and always caused an extraordinary and rapid increase in the rate and extent of the respiration. Thus I have seen the respiration, which had practically ceased for ten seconds, suddenly, under the influence of an injection of two-tenths of a grain of strychnine, become at once very large and full, and reach a rate of 130 a minute.

A series of elaborate experiments made upon the effect of the position of the animal on the blood-pressure in the carotid and other arteries, has very clearly proven that the body of the animal whose circulation has been

paralyzed by chloroform, acts in a measure like a tube filled with fluid. Thus, if the feet of the dog were raised vertically above the head, whilst the latter remained upon the table, an immediate rise of pressure occurred, even though the heart had entirely ceased beating; provided that the head of the animal was kept upon a

FIG. 10.



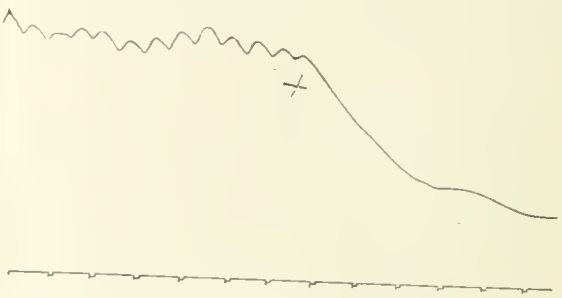
Tracing showing effect of injection of strychnine, after breathing had ceased, in an advanced chloroform anæsthesia. 0.193 grain of the sulphate was injected at X.

level with the table. If, however, the head of the animal was depressed below the level of the table for a distance equal to, or greater than the length of the body of the animal, a decrease of the arterial pressure occurred at once, although the animal was in a vertical position. The phenomena observed were precisely such as would have been produced if the canula had been inserted into a tube filled with fluid, instead of into the carotid artery, and the elevation and depression of this tube had registered itself on the recording drum, in obedience to the ordinary laws of hydrostatics. The phenomena were entirely independent of any beat of the heart, and were readily produced when the animal was dead, provided the death had not occurred too long previously. Sometimes, even a very few minutes after the cessation of the heart-beat, it was impossible to produce the changes of pressure upon the drum. This I believe to have been due to coagulation of the blood, occurring very early after death to a sufficient extent to interfere with the liquid properties of the fluid. In no case was any effect upon the respiration produced by change in position of the animal. In a number of cases, however, when the feet were elevated, the heart, which had entirely ceased beating, recommenced its work, and I have several times seen a pulse entirely disappear when the animal was taken from the vertical to the horizontal position. On the other hand, very frequently it was impossible to affect the cardiac action by changing the position of the animal. Nevertheless, the phenomena spoken of occurred too frequently to be a mere outcome of chance, though I several times noted that the heart was usually more affected by alternately elevating and depressing the feet of the animal, than by keeping it in a steadily elevated or horizontal position.

When the circulation has practically ceased, under the depressing influence of an anæsthetic, inverting the body must cause the blood which has naturally collected in the enormously relaxed vessels of the abdomen, to flow into the right side of the heart and distend it, and this distention—this increase of pressure—appears at times to have a sufficient momentary influence to stimulate the failing organ.

The theory which has been advocated by some therapeutists, that inversion of the body is of value in the accidents of anæsthesia, because it causes the vital centres of the brain to be supplied with blood, is proba-

FIG. 11.



Tracing showing effect upon the heart of a dog which had been vertical, with his head on level of the table, of bringing him into horizontal position. Feet dropped at X.

bly incorrect. The respiration in anæsthesia fails, not through want of blood in the respiratory centres, but because the blood contains a poison which paralyzes these centres.

The most remarkable results which I have reached in bringing about recovery of animals to all ordinary intents and purposes dead, were obtained through the use of artificial respiration. Thus, I have seen an animal, in which no respiratory movements whatever had taken place for two minutes, and in which, during that time, no movements of blood had occurred in the carotid artery, and in which, therefore, the heart had ceased to beat, rapidly and permanently restored by artificial respiration.

At one time in these researches, it appeared as though after any dose of chloroform by inhalation the animal could be resuscitated by artificial respiration, even though heart and lungs were completely paralyzed by the drug; but finally I did find a case in which artificial respiration failed.

The results of my experiments with the lower animals may be summed up: that nitrite of amyl, caffeine, and atropine are of little or no use in chloroform-poisoning; that alcohol, when given in small amounts, has no influence, but that when given largely materially assists in paralyzing the heart and producing fatal results; that ammonia has some little influence upon the heart, but that of all substances tried, digitalis is by far the most powerful in stimulating the failing circulation; indeed, my experimental results indicate that it is the only known drug which is of any real practical value in such cases. Next, or perhaps even before digitalis, strychnine seems to be of value in the accidents of anæsthesia, because, whilst having some influence on the circulation, it powerfully affects the respiration. For many years chloroform has been used in practical medicine as the physiological and practical antagonist to strychnine, and it seems rather odd that strychnine should

never have been employed as the practical antagonist to chloroform.

The one measure which in practical value far surpassed all others for the restoration of the dying animal was artificial respiration, and I have no doubt that a great majority of the deaths which have occurred in man from anæsthesia might have been avoided by the use of an active artificial respiration. The difficulty with artificial respiration as it has been hitherto practised upon man, after the Sylvester or other methods, is its inefficiency; whereas the artificial respiration which I used on animals was very active—indeed, much more efficient than natural breathing in causing circulation of air through the lungs, and therefore in removing excess of the anæsthetic from the residual air in the lungs, and from the blood.

The use of what may be called "forced" artificial respiration by the physiologist, so naturally suggested a similar practice in man, that the celebrated John Hunter invented for the purpose an apparatus which consisted of a bellows so constructed that when it was extended one compartment drew in air from the lungs, whilst the other drew air from the atmosphere; and when it was closed the process was reversed, the fresh air being thrown into the lungs, the foul air into the atmosphere. In 1867, Richardson, of London, invented an apparatus more elegant and portable, although identical in principle with that of John Hunter's; but I have not found that either Hunter or Richardson treated by forced artificial respiration an actual case of disease or poisoning. In 1875 (*Boston Medical Journal*, vol. xxi.), Dr. John Ellis Blake reported a successful case of aconite-poisoning, in which life was apparently saved, although there was no pulse for over three hours, by artificial respiration, with the use of oxygen. In this case Marshall Hall's method was at first used, but later, a small rubber tube was connected directly with a copper reservoir of condensed oxygen, the other end of the tube terminating in a small nozzle, which was inserted in one nostril. Four hundred gallons of oxygen were thus used, but how far the force of the compressed gas was employed to dilate the lungs is not very clear; and it is somewhat doubtful whether this case should be considered as one of forced respiration. The first physician to use forced respiration in actual human poisoning, with a clear idea of its value and power, so far as my reading goes, was Dr. George E. Fell (*International Medical Congress*, Washington, 1887).

It is plain that the bellows constructed by John Hunter and by Richardson are unnecessarily complex and faulty in principle, There is no need whatever of drawing the air out of the fully filled lungs. Every physiologist knows that when the muscular system is completely paralyzed by woorari or even by death, that the chest-walls have sufficient elasticity to force air out of the lungs, and all ordinary laboratory apparatus for artificial respiration is based upon this fact. For forced artificial respiration in man an ordinary bellows of proper size is all that is required for the motive power.

The real difficulty—the point to be especially investigated and studied—is as to the connection between the bellows and the lungs. Hunter and Richardson simply placed a tube in one nostril, closing firmly the other nostril and the mouth of the subject.

Dr. Fell at first used a tracheal tube, the insertion of which, of course, necessitated the performance of tracheotomy. In one case, however, a simple mask covering the mouth and nostrils was a perfect success. I have had no opportunity of trying the apparatus on the living, but have made a series of experiments upon dead bodies, which have demonstrated that usually a face mask is all that is necessary for the performance of artificial respiration. Before using the mask the tongue should be well drawn forward, and, if necessary, fixed in this position by an ordinary piece of suture silk run through it, which can be held in the hand of the operator. If in any individual case the mask fails, an intubation tube may be introduced into the larynx. I do not believe that it is ever necessary to perform tracheotomy.

Dr. Fell's apparatus consists of a pair of foot-bellows by which air is forced into a receiving chamber, which is connected with an apparatus for warming the air, and a valve which can be opened and shut by a movement of the finger. This valve in turn leads to the tracheal tube. When the valve is opened the air rushes through the chamber into the lungs and expands them; the finger is lifted, the valve shuts, the lungs contract; and so the respiration goes on. I have no doubt that this apparatus is very efficient in practice, but it is open to the serious objection of being unnecessarily complex and costly.

A much simpler, cheaper, and probably equally efficient apparatus may consist simply of a pair of bellows of proper size, a few feet of India-rubber tubing, a face mask, and two sizes of intubation tubes; there should also be set in the tubing a double tube, with an opening similar to that commonly found in the tracheal canula of the physiological laboratory, so that it is in the power of the operator to allow for the escape of any excess of air thrown by the bellows. I suppose this whole apparatus could be prepared at the expense of less than five dollars, and it seems hardly necessary to point out the probable value of this simple apparatus in various narcotic poisonings, and other accidents in which death is produced by a paralysis of the respiratory centres, of temporary nature. The proper use of it could be taught to persons without special medical skill, so that it not only ought to form a part of the surgeon's outfit, but might be of great service in life-saving stations, about gas-works, etc.[1]

In conclusion, I may be allowed to state, that if the results and deductions arrived at in this address are, as I believe, correct, the rules for the proper treatment of accidents during anæsthesia can be summed up in a very few words:

Avoid the use of all drugs except digitalis and ammonia.

Give the tincture of digitalis hypodermically.

Draw out the tongue, and raise up the angle of the jaw, and see that the respiration is not mechanically impeded.

Invert the patient briefly and temporarily.

Use forced artificial respiration promptly, and in protracted cases employ external warmth and stimulation of the surface by the dry electric brush, etc., and above all,

[1] Messrs. Charles Lentz & Sons, Philadelphia, can furnish the apparatus for artificial respiration at a cost of $8.50.

remember that some at least, and probably many of the deaths which have been set down as due to chloroform and ether, have been produced by the alcohol which was given for the relief of the patient.

INTERNATIONAL UNIFORMITY IN ARMY MEDICAL STATISTICS.

An Address delivered before the Section of Military Hygiene, Tenth International Medical Congress, Berlin, August 7, 1890.

BY JOHN S. BILLINGS, M.D., LL.D.,
SURGEON UNITED STATES ARMY.

"CAN the sick-lists and sanitary reports in the different armies be made up after a pattern uniform at least in essentials, in order to obtain statistics which may furnish data of scientific worth for comparing diseases, wounds, and deaths occurring in the different armies in times of peace and war?"

In attempting to comply with the request with which I have been honored, that I should prepare a paper in answer to this question, I propose to consider the subject under the following heads:

I. What are the most important data which can be obtained for the preparation of such statistics?

II. What are the principal combinations of these data which have been given in army medical statistics heretofore published?

III. Which of these data, or combinations of data, are most important to the individual command or army, or country, for purposes of military administration?

IV. What are the most desirable combinations of these data for publication for the purpose of increasing our knowledge of the laws of health and disease by comparison of the mortality and morbidity statistics of different armies in times of peace and war?

V. What forms of returns and reports are best calculated to secure the data desired, as specified under III. and IV., *supra*, with accuracy, promptness, and completeness?

VI. Will it probably be possible to induce the different Governments to agree to a uniform system of publication of the data and combinations of data recommended as desirable in answer to question IV.?

Let us consider these several points in the order stated, and for the sake of brevity and simplicity I shall first speak with regard to diseases only, and as to those occurring in times of comparative peace.

The data given in the reports of army medical officers relating to individuals taken sick or injured, relate to

1. Locality of the post.
2. Arm of the service, as { Artillery. Cavalry. Infantry, etc.
3. Rank—*i. e.*, { Commissioned officers. Non-commissioned officers. Privates.
4. Occupation prior to enlistment.
5. Length of service.
6. Age of the individual.
7. Race or nationality (including color distinction).
8. The date of occurrence of the disease or injury.
9. The nature of the disease or injury.
10. Complications and sequelæ of the disease or injury.
11. Results, including length of time of treatment required:
    - *a.* Returned to duty.
    - *b.* Transferred.
    - *c.* Discharged.
    - *d.* Invalided.
    - *e.* Died.
    - *f.* Otherwise disposed of.

Of these the most important in the order named are the nature of the disease or injury; the result; age; date of occurrence of affection; the number of days of treatment; locality of the post or station; the period of the year; the length of service; the arm of service; rank; race; and occupation prior to service. To permit of comparisons and the calculation of percentages, there is also needed information as to the mean strength of the command during the period under consideration, with distinction of arm of service, rank, and color, and for some purposes with distinction of age, race, or nationality, length of service, and previous occupation.[1]

The following are the formulæ of some of the tables occupying the greatest amount of space in the published medical statistics of different armies. The data indicated by the letters are shown in the foot-note, the exponential figures after certain letters show the number of subdivisions of that item, thus: C (199) indicates that the figures are given for 199 different causes of admission to sick report. L (53), that they are given for 53 different localities, etc. The symbols to the left of the perpendicular line indicate the headings in the first or left-hand column of the table, while those to the right of the same line show the headings at the top of the remaining columns:

Austrian Army.

C. (194)	T. t. / D.	L. (16) — A. S. (11).	4 pages quarto.
C. (194)	T. t. / D.	A. S. / L.	36 pages quarto.

[1] The following are the abbreviations used to designate these data in the formulæ of tables given hereafter:

A.	Age.
Ad.	Admission.
A. S.	Arm of Service: Infantry, Cavalry, etc.
C.	Cause of admission to treatment.
Col.	Color.
D.	Deaths.
Di.	Discharged.
D. t.	Days treated.
Du.	Returned to duty.
I.	Invalided.
L.	Locality.
L. S.	Length of Service.
M.	Months.
M. S.	Mean Strength.
O.	Occupation prior to enlistment.
O. d.	Otherwise disposed of.
R.	Remaining on hand.
Rnk.	Rank: Commissioned Officers, Non-commissioned Officers, Privates.
S.	Seasons.
T. d.	Total disposed of.
Tr.	Transferred.
T. t.	Total treated.

Bavarian Army.

C. (199) | $R. + \frac{Ad.}{M.} + \frac{T.\,d.}{Du. + D - O.\,d.} + R. + D.\,t.$ — 36 pages quarto.

L. (53) | $M.S. + Ad. + D. + \frac{C.(37)}{Ad. \quad D.} + Di. + I.$ — 10 pages quarto.

Belgian Army.

C. (24) | Ad. + T. d. + D. + D. t. — For 22 localities in separate tables. 11 pages octavo.

C. (185) | Ad. + T. d. + D + D. t. — 5 pages octavo.

British Army.

{ M. S. / C. (39) | Ad. + D. + (Di. + I.). — Separate tables for 29 principal localities and many subdivisions of localities. 62 pages octavo.

A. (7) | M. S. + Ad. + D. — I.

L. S. (8) | M. S. + Ad. + D. + I.

A. S. | M. S. + Ad. + D. + I. + L. — 40 pages octavo.

French Army.

M. S. | L. (377).

C. (27) | $\frac{L.\,(377)}{Ad.} + D.$ — 45 pages quarto.

D. t. | L. (377).

A. S. (10) | $\frac{M.\,S.}{Rnk.\,(3)} + L.\,S.\,(2) + A. + Ad. + D.\,t. + I. + D.$ — 46 pages quarto.

C. (27) | $R + \frac{Ad.}{Rnk.\,(3)} + L.\,S.\,(2) + T.\,t. + D.\,t. - A.S.\,(24).$ — 2 pages quarto.

German Army.

C (199) | $R + \frac{Ad.}{M.} + \frac{T.\,d.}{Du. - D. \quad O.\,d.} + R. + D.\,t.$ — 15 pages quarto.

L. (319) | $M.S. + A.\,d. + D. - \frac{C.\,(37)}{Ad. + D.} + Di. + I.$ — 53 pages quarto.

M. | $M.S. + \frac{Ad.}{C.\,(37)}$ for each of 16 army corps. — 46 pages octavo.

Italian Army.

A. S. | M. S. + Ad. + D. + Di. — D. t. — 30 pages octavo.

C. (102) | L. (93) — Ad. — 12 pages octavo.

C. (102) | L. (93) + Ad. — 12 pages octavo.

Netherlands Army.

L. (37) | $\frac{C.\,(24)}{Ad.}$ — 2 pages octavo.

U. S. Army.

C. (46) | $\frac{L.\,(182)}{Ad. + D. + Di.}$ — 74 pages octavo.

L. (182) | $M.S. + \frac{C.\,(2)}{Ad.} + Di. + D.$ — 20 pages octavo.

The principal combinations of data heretofore used in regular periodical reports, including both those relating to the sick and injured, and to all men of the command, are shown in the following tables, which indicate the data, and combinations of data, given in medical statistical reports of the Austrian, Bavarian, Belgian, British, French, German, Italian, Netherlands, and United States armies in recent years:

		Austrian army.	Bavarian army.	Belgian army.	British army.	French army.	German army.	Italian army.	Netherlands army.	U. S. army.

In the above tables the cross indicates that the special data, or combination of data, indicated in the left-hand column, are given in the statistical reports of the medical department of the army indicated in the heading of the perpendicular column. The circle indicates that the data, though not given directly, are given in some other combination indicated by a cross in the same column. It will be seen, for example, that the important datum of age is only given for the mean strength of the commands in the periodical reports of the French, British, and United States armies, and that, therefore, it is impossible for all other armies to make comparisons as to the proportion of soldiers of each group of ages who are affected with disease or injury. The age-grouping of those taken on sick report is given only in recent annual reports of the British and United States armies; it is given for those discharged or invalided in the German, Italian, Bavarian, British, and American reports only; for those who died, in the German, Bavarian, French, Belgian, British, American, and Italian reports, and it is not given at all in any army medical report in relation to the average number of days of treatment. Moreover, the age-groupings used in different army reports do not correspond to each other, nor, which is more important, to the age-groupings used in published vital statistics of civil life, as will be seen by the following table:

TABLE SHOWING AGE-GROUPINGS IN DIFFERENT ARMY MEDICAL REPORTS.

Keeping before us this bird's-view of what has been attempted in published military medical statistics, let us proceed to our third question, viz.: Which of these data, or combinations of data, are most important for local military administration?

Evidently they are those which show the actual effective strength of the command, and the causes of its diminution. The actual number on sick report, the number returned to duty, died, discharged or transferred must be given on the daily, weekly, and monthly reports for the immediate information of commanding officers. We need only consider the tables to be published, which will, for the most part, be yearly summaries relating to the total treated or excused from duty during the period to which they relate. The distinction between the "number admitted," the "number treated," and the "number disposed of" must be borne in mind, for these are not the same—they have different statistical uses and values—and cannot be directly compared with each other. The "number treated" includes the number remaining under treatment at the beginning of the period and the number admitted during the period. Those remaining under treatment at the end of the period are, of course, included in this sum. It is, therefore, greater than the "number admitted," and in most cases greater than the "number disposed of." The number of admissions may be either equal to, or greater or less than the "number disposed of," depending on the difference between the number under treatment at the commencement and the number remaining under treatment at the close of the period. The form of table most useful for these administrative statistics is one like the following, which shows for the command the mean strength, number taken on sick report, number died, number discharged, number transferred or otherwise disposed of, average number of days sickness to each soldier, with distinction of certain causes or groups of causes.

Station ..... Period .....

Mean strength of the command:

Officers .... Enlisted men ..... Total strength .....

Tabular List of Diseases. The names of diseases not printed below, and the number occurring during the month, will be written under the class to which they belong.	Remaining under treatment from last report.	Admitted.	Total treated.	Number of days' treatment.	Returned to duty.	Discharged or invalided.	Died.	Otherwise disposed of.	Remaining under treatment.
Smallpox									
Other acute contagious fevers									
Diarrhœa									
Dysentery									
Typhoid fever									
Malarial fever									
Venereal—Primary syphilis									
Venereal—Secondary "									
Venereal—Gonorrhœa									
Septic diseases									
Pulmonary phthisis									
Other tubercular diseases									
Etc.									

Such tables may be given in more or less detail, for each month or year, for different localities, regions, ranks, arms of service, for those under and over one year in service, or for other units of military administration. The death-rates and discharge-rates may be given for these units, but for most individual causes of sickness or death the numbers are too small to make it worth while to calculate ratios except for groups including 25,000 men and upward, or for periods of five or ten years. The ratios derivable from half a dozen cases, or less than half a dozen deaths, are, for the most part, of little value, owing to the law of probable error in relation to number of individual data, although it would be easy to indicate possible exceptions to this rule. It appears to me that it is sufficient to publish details as to causes for separate posts and garrisons, and for months or seasons, by periods of five or even of ten years. The statistics of principal causes of disease in relation to locality would certainly have more scientific value if compiled for the longer period, in connection with the information derived from sanitary reports as to soil, climate, altitude, drainage, water-supply, buildings, duties of troops, etc.

The particular forms of disease of most interest in the administrative point of view, can best be discussed in connection with my fourth question, viz.: What combinations of these data are most desirable in publication for the purpose of making reliable and useful comparisons of the medical statistics of different armies in times of peace and war respectively?

These are the statistics which are to be published a long time after the events with which they are concerned have occurred, and whose importance, for the purpose of international comparison, is in proportion to the possibility of increasing by them our general stock of knowledge of the laws of health and disease.

We have to consider death-rates and sick-rates, mortality, and morbidity. As regards general or gross death-rates, they depend so much upon the proportion of discharges for disability, which in turn depend upon whether service is voluntary or compulsory, and for long or short terms, that for armies which differ in these respects no useful comparisons can be made. The death-rates from acute forms of disease in armies are much more valuable for purposes of comparison with each other and with the corresponding rates in civil life, but for the latter purpose they should be given by age-groups. The special value of army medical statistics for scientific purposes lies in the sick-rates, for these are our chief source of information with regard to the number of cases of disease occurring in a given number of adult males in a given time under different conditions of climate, locality, etc. General or gross morbidity rates in armies are not valuable for purposes of comparison unless they include substantially the same class of facts. Where the soldier is officially taken up on the sick report whenever treated by the medical officer, no matter for how short a time, or for how trivial a cause, or whether excused from all duty or not, the

sickness-rate will, of course, be higher than where this is not the case. It is in the special sickness-rates and death-rates, due to certain diseases or groups of diseases, and in the relation of these to age, nationality, race, season, and conditions of environment, that the scientific value of army medical statistics chiefly consists.

What are these diseases or groups of diseases which are thus specially important, and the data for which should be rendered comparable in the published reports of different armies?

As regards individual forms of disease, the most important, and those for which the data are in most of the published reports given in more or less detail are the following, viz., smallpox, typhoid fever, diarrhœa, dysentery, malarial fevers, syphilis, gonorrhœa, pulmonary phthisis, pneumonia, acute bronchitis, tonsillitis, scurvy, alcoholism, diabetes, rheumatism, malignant tumors, mental disorders, and suicides.

Let us consider these briefly. The statistics of smallpox in an army indicate the relative completeness with which vaccination and revaccination have been carried out among the men, and thus furnish a test of the administrative efficiency of the medical department, and a demonstration of the importance of these measures in civil life; but there is no probability that the army statistics of this disease will add materially to our knowledge of its causes, pathology, or treatment. It is useless to give details with regard to the cases. All that need be stated is the total number of cases, number of deaths, and the condition of the command, and of those affected, as to vaccination. The number of cases of typhoid fever, diarrhœa, and dysentery, form the chief test as to the character of the water supplies. Recent advances in bacteriology have made it improbable that the most elaborate statistics of these affections will materially increase our knowledge as to their causes or pathology, though the field is still open for the collection of data as regards sequelæ and treatment. Here again, then, the statistics must be considered to be chiefly useful as a means of measuring local efficiency of administration, and of testing results obtained in the laboratory.

With regard to typhoid fever there is one important question which might be answered from army medical records, and that is as to the amount, or proportion, of immunity conferred by the first attack of this disease. What proportion of men subjected to the influence of the specific cause of typhoid are attacked a second or a third time by this disease, at what ages, and at what length of time from the previous attack? To answer this question it will be necessary to make a special inquiry with regard to each man serving at a post in which typhoid fever prevails, noting whether he states that he has or has not had this disease, in case of an affirmative answer, when and where, and the duration and severity of the attack, his present age, and his length of service.

In many cases the answers would no doubt be vague or unreliable in themselves, but in many such cases, by referring to previous army medical records, or by correspondence with the physician who is said to have attended him, it would be possible to ascertain whether the disease was really typhoid or not. The results of such an inquiry can only be approximate, but they would certainly be interesting and valuable. By the system of card records, which will be described hereafter, the results of a series of years of experience on this point would be brought together.

The statistics of malarial fevers are chiefly interesting in their relations to locality and as contributions to geographical pathology. Differences of race, and especially of color where these occur, should be indicated in such statistics, but elaborate combinations of rank, length of service, previous occupation, etc., cannot be expected to increase our information with regard to these diseases.

The statistics of venereal disease in armies are of general as well as of local importance, since they furnish data from which to judge of the merits of various schemes which are proposed for their diminution in civil life. The statistics of scurvy, like those of smallpox, are merely a test of the efficiency of the administration of an army, and cannot be expected to add to our knowledge of this disease, except, possibly, as regards methods of treatment. The statistics of alcoholism, while chiefly important as bearing on local administration, have also a considerable value from a sociological point of view, and should be given in some detail by groups of ages, with distinction of rank and of arm of service, and, as far as possible, the results observed. The distinction between acute and chronic alcoholism should be insisted on.

For pulmonary phthisis, and, in fact, for tubercular diseases in general, the recent advances in our knowledge as to the essential cause enables us to put more definite questions than was heretofore possible, which may be answered, to some extent, at least, by army medical statistics. The prevalence of this disease in a body of troops taken in conjunction with the statistics of cases of inflammatory affections of the throat, such as tonsillitis, affords a very good test as to the efficiency of the ventilation of the barracks and quarters of the men. It is not meant by this to assert that defective ventilation is the only cause of these affections, but, whenever they are found to prevail in unusual proportions, it will usually be found that the men have been unduly exposed to a defective and impure air supply.

The number of cases of insanity and suicide attempted or effective which occur in an army are of special interest when the data are given in connection with distinctions of age, race, rank, and length of service. If given for comparatively short periods, as for a single year, the numbers are usually insufficient to do more than indicate points to be especially attended to in administration. It is for periods of five or ten years that statistics of these affections are the most likely to be of scientific value and interest. The same may be said with regard to statistics of tumors of all kinds, and especially of the malignant forms of the sarcomas, myxomas, and true epitheliomatous growths. It is known that these occur in different proportions in different races and at different groups of ages. But there are many points in regard to this class of affections in relation to which an international statistic, derived from the records of the large armies of different countries for a period of years, indicating their relative frequency in different parts of the body, etc., would be of great interest.

CLINICAL OBSERVATIONS ON DIPHTHERIA AND DIPHTHERITIC PARALYSIS, WITH SPECIAL REFERENCE TO TREATMENT.[1]

By JAMES HENDRIE LLOYD, M.D.,
PHYSICIAN TO THE HOME FOR CRIPPLED CHILDREN, PHILADELPHIA.

During the last winter and spring diphtheria prevailed quite extensively in Philadelphia. It was probably not as virulent and fatal a type of the disease as has prevailed at some other times, but it nevertheless caused many deaths. Variations in its severity make it difficult to estimate with accuracy the merits of different plans of treatment, and may also have something to do with variations in the prevalence of one of the most formidable complications of the disease, namely, paralysis. Observation and inquiry have led me to believe that this particular sequela (or as I prefer to call it, complication) has been noted rather more frequently of late than in former years; but I do not infer from this fact that paralysis is a more common result than formerly, but, rather, that the complication in minor degrees is more readily recognized by the practitioner, because of the more general cultivation of neurological science.

Although more than twenty years have passed since Oertel announced that a micrococcus was always present in the membrane and in the blood of diphtheritic patients, and broadly stated that "without micrococci there can be no diphtheria," the time has not yet come for us to abandon the clinical for the bacteriological study of this important disease. The weight of opinion seems to be that the specific poison of diphtheria is either a bacterium or the ptomaine generated by it. This gives us at least a working theory, upon which we can hope to establish, if not a specific, at least an active and even aggressive treatment. For the rest we must be content to leave the, perhaps yet unsolved, problem of the exact form and habits of the specific microbe to the numerous workers in this field of medical research.

The pathology and morbid anatomy of diphtheria, especially in the cerebro-spinal system, while a question of great interest, is not one which will especially detain me. The action of this poison, whatever it is, upon nerve-tissue is so distinctly like that of other morbific agents whose action is fairly well known, that there is little doubt that it acts especially upon what Gowers calls the "lower segment" of the nervous system; that is, the large cells in the anterior horns and the nerve-fibres running out from them to form the nerve-trunks. That some observers have located the lesions in the horns and others in the nerve-fibres only furnishes additional evidence that these two parts form really one anatomical organ, and that the diphtheritic poison acts probably upon the whole. It might even be claimed on good clinical evidence that it is a general protoplasmic poison, which does not confine itself to one group of cells, just as arsenic, alcohol, and some other substances, whose effects upon nerve-tissue are not unlike those of diphtheritic poison, are known to attack many tissues of the body.

The similarity of action upon the peripheral nervous system of these several poisons seems to me to furnish some important indications not only for treatment, but, what is of equal importance, for prevention, and finally for prognosis. The clinical picture of a peripheral neuritis—with perhaps also an associated anterior poliomyelitis—is perfectly delineated in post-diphtheritic paralysis, and associates it at once with the general peripheral neuritis which in recent years has been so successfully studied. From this association we gain additional insight into pathology and some important hints in therapeutics.

If, in the first place, we may assume that a violent protoplasmic poison is being generated in the body, we have the first and I believe the most important indication, viz., to prevent its generation, as far as possible, by early local treatment. Secondly, having the lesions of a peripheral neuritis, we have some ground upon which to base an intelligent prognosis, and an efficient, although somewhat expectant, treatment.

As this scheme includes of necessity the treatment of the primary disease, I desire to offer a few observations on the subject.

Chlorate of potassium seems to be losing the confidence of the profession in the treatment of diphtheria, because it is known to have, in large doses, an injurious effect upon the kidneys. Some therapeutists even say that it is responsible for some of the deaths in this disease. It is probably a safe drug if given in doses aggregating less than a drachm a day to young children—the condition of the urine being watched. I speak of it now only to recommend as a substitute the chloride of ammonium. I have observed the use of this remedy in diphtheria for twelve years, and know of its successful use by another practitioner for a much longer period. Our knowledge of the effects of chloride of ammonium, as of chlorate of potassium, in a specific disease like diphtheria is mostly empirical, and on this basis I feel justified in saying that the former will do all that the latter drug can do and without its injurious effects. The physiological action, however, of chloride of ammonium[1] indicates, to a certain extent, its therapeutic use. It

[1] Read at the annual meeting of the American Neurological Association, Philadelphia, June 5, 1890.

[1] See Ringer's Therapeutics.

acts as a stimulant to the mucous membrane, increasing the normal secretion and so diluting and dissolving thick, tenacious mucus and fibrinous masses. That it has any true antiseptic action, either locally or in the blood, cannot be affirmed, and the same must be said of the chlorate of potassium in safe therapeutic doses. It is eliminated unchanged in the urine,[1] and without any apparent irritating effects upon the kidneys. The chloride of ammonium makes an admirable mixture with the tincture of the chloride of iron, and in combination with this invaluable drug constitutes a remedy for diphtheria in which experience has taught me to place an unusual degree of confidence. The tincture of the chloride of iron is in itself the one remedy which seems to hold its place in the esteem of every practitioner. Such universal testimony cannot be without great weight. It is most important that this remedy should be applied locally and thoroughly to the membrane. A mixture of one-half drachm each of the iron and of the chloride of ammonium to one ounce of a thick syrup (preferably of tolu) may be administered internally every two hours in teaspoonful doses, and at the same time a soft camel's-hair throat-brush is to be used to apply the mixture thoroughly to the diseased parts. It is not enough to direct the patient to hold the dose in the throat against the soft parts before it is swallowed. Many patients are too young to do so, and no one can do it efficiently. Internally it may be given every hour in bad cases, but the application by the brush every two hours, if done properly, is sufficient. It is very probable that the tincture of the chloride of iron is antiseptic when thus directly applied to the exudate, which we have reason to believe swarms with pathogenic organisms, while the chloride of ammonium, by increasing the mucous secretions of the throat and mouth, assists to dissolve and loosen this mass and promotes its expectoration. All evidence of value furnished by modern research tends to prove that diphtheria begins—and often continues for a long time—as a local affection. It is from this focus that the living germs of the disease gain admission to the lymph-spaces and bloodvessels. It is here that the distillation of protoplasmic poison probably begins, and it is here, reason teaches, that the disease must be combated with vigor at the very outset.

During the past winter I frequently tried the calomel treatment and have confidence in it, but I cannot say that I have seen as prompt results as from the treatment above described. I have usually given a fractional dose ($\frac{1}{4}$ to $\frac{1}{8}$ of a grain) every hour or two, according to the severity of the case. I do not believe it necessary or desirable to give the heroic doses recommended by some—5 grains every one or two hours. Such doses weaken the patient by the violent cathartic action almost always excited, and it is doubtful if more constitutional impression is made by these giant doses, as much of the substance is probably not absorbed. It is not certain that calomel acts thus locally as a germicide, and I am positive that its administration should be accompanied with an antiseptic wash or spray to the throat and nose. The substances which are useful for this purpose are boric acid, oxide of lime, sulphur, oil of eucalyptus, and carbolic acid, variously combined. The extract of pancreatin may be added on theoretic principles. In the use of the spray it is of the utmost importance that the nasal chambers be cleansed. To neglect this is to neglect half the field. Although I believe this treatment by calomel is good, I must say that I have seen an obstinate diphtheritic membrane which did not yield to it for a week melt away rapidly under the treatment by iron and ammonia above described.

The corrosive chloride of mercury appears on some accounts to be the model remedy for diphtheria, and it can be used both locally and internally. As an antiseptic spray it probably has no superior. It can be used as strong as 1 to 4000 (and in some cases stronger). The amount which thus enters the stomach is small and promotes the cure. It can be combined for internal use with the tincture of the chloride of iron ($\frac{1}{48}$ to $\frac{1}{24}$ grain in three to eight drops of the iron) and given every two hours. I think that the exceedingly small doses ($\frac{1}{96}$ to $\frac{1}{72}$ grain) recommended by some are of little use unless in the case of very young children. It is necessary, of course, to watch for symptoms of stomachic irritation.

It is not within the scope of this paper to present a complete statement of all forms of treatment which are approved by different authorities. Other germicidal agents than those mentioned are salicylic and carbolic acids and turpentine. The recent researches of Roux and Yersin[1] demonstrate again how important is the local, disinfecting treatment. As between the spray and the brush, I think that the latter is often the more effectual for the fauces, while the spray is necessary for the nasal cavities. Some object that local applications by the brush are irritating and alarming to very young children. In my experience they are not as much so as is the spray through the nose, and can generally be managed with a little tact. Medicated vapors in the room are too dilute to be of any importance.

[1] Parkes, quoted by Ringer.

[1] Revue Mensuelle des Mal. de l'Enf., abstracted in Arch. of Pædiatrics, April, 1890.

The recognition of diphtheritic paralysis as a toxic neuritis, caused by poisonous products of the local disease, demands that this set of symptoms be no longer regarded as a rare sequela of only special interest, but as part of the general symptom-group, some evidence of which may be found in very many more cases of diphtheria than is generally supposed. Bernhart, for instance, pointed out that the knee-jerk is abolished in many cases of diphtheria which do not exhibit distinct paralytic symptoms. This, as Gowers says, is only part of a broader fact. This fact, it must be emphasized, is that a toxic agent begins *early*, and probably in *all* cases, to threaten the integrity of the peripheral nervous system.

Another, and much more alarming symptom, is the heart-failure which so suddenly and with little warning sometimes terminates life. This is probably due to involvement of the vagus—at least, all the symptoms indicate such involvement. It is usually observed earlier than other paralytic symptoms, but it is a mistake to suppose that it never appears after them. I once observed the symptom in a case of multiple neuritis of alcoholic origin; the patient, a woman, suddenly collapsed, and died in a few minutes of heart-failure. The following case illustrates this complication:

A boy, aged seven. The disease began with a chill and sore-throat. In a few hours a membrane began to form on one tonsil, and in two days had spread over both tonsils and the back of the pharynx. There were great enlargement of the glands, earache, and a purulent discharge from the nose. The calomel treatment was actively pushed, the throat and nose frequently sprayed, and careful attention given to his nutrition. By the end of the tenth day the membrane had disappeared, the glandular swelling was gone, the pulse was between 90 and 100, and the patient was convalescent. On the eleventh day he suddenly became sick and began to vomit; had pain in the epigastrium, and grew deadly pale, while his pulse increased in frequency and was very small. Nerve and heart stimulants had not the least effect upon the symptoms. On the twelfth day he was inclined to play with his toys; his vomiting had ceased, but the pallor and the feebleness of the heart continued. He suddenly screamed out with pain in his leg along the great vessels, and in a few moments was dead. I think the pain in his leg was caused by a dislodged embolus from the enfeebled heart.

Another case was seen by me for a fellow-practitioner who said that the child was convalescing from diphtheria. A change had occurred during the day, and when I saw the child she was almost pulseless, although the mother had noticed nothing. The patient died in a few hours.

In another case, in a rural district, as soon as the child was apparently well, the parents most unwisely took it out for a ride. When they brought it home it expired soon after being taken into the house.

In these cases there were no other paralytic symptoms. The force of the poison seemed to be exerted upon the cardiac apparatus, and, most probably, upon its nerve-supply. If these children had lived it is possible that some of them would have had paralysis of other parts.

In the general multiple neuritis of diphtheritic origin the prominent symptoms are often not noticed for several weeks after the disappearance of the primary disease. It is thus customary to say that they appear suddenly, and that the poison, whatever it is, has lain dormant in the system for a long time, but the observation of Bernhart, already alluded to, that the knee-jerk is absent in many cases, must make us cautious about accepting this opinion as final. I have had reason to believe that these symptoms have often been insidious in their approach, and hence unnoticed. If a child has only an abolished knee-jerk, and continues listless, the actual state may readily be overlooked; even a slight nasal twang in its voice might escape notice; until at last regurgitation of fluids, head-drop, and an ataxic gait force attention. I had a case recently which illustrates some of these facts:

A boy, aged five years, had extensive pharyngeal diphtheria, with swollen glands. He was treated with the chloride of ammonium and tincture of the chloride of iron internally, and the same remedies were thoroughly applied with a brush to the throat at frequent intervals. He made a good recovery, and had no nerve symptoms, unless it was the weakened patellar reflex. After an interval of five weeks he was again brought to me in a bad condition. He could not articulate clearly; the soft palate was flaccid and rather anæsthetic; the left eye had convergent squint (paralysis of sixth nerve). There was no paralysis to light or of accommodation, although the latter was not tested by near objects, as the boy could not read. He had head-drop, caused by paralysis of the muscles at the back of the neck; there was loss of power in the forearms; the patellar reflexes were abolished; cutaneous sensibility was difficult to test. This child was admitted at once into the Home for Crippled Children, and under care and treatment recovered. On inquiry I found that the symptoms had been coming on very gradually. These were strangling, regurgitation of fluids, dropping of the head, and a staggering gait. When strabismus became marked the parents were alarmed and sought advice. There was probably no time after his supposed recovery from the diphtheria that nerve lesion in some minor degree, shown by abolished patellar reflex, ataxia, and nasal speech, could not have been detected by a more careful examination.

The lesson to be drawn from this case is obvious. The physician should not think his duty done when he has cleared away the membrane and established convalescence. If he remembers that he has had to combat a nerve poison, which in many cases shows

its effects almost from the start, he will be guarded in his prognosis and more expert in detecting early symptoms.

The treatment of diphtheritic paralysis itself is mainly expectant. The nerve lesions demonstrated in the autopsies of these cases are degenerative—destructive; they are the lesions especially of parenchymatous neuritis—*i. e.*, destruction of the axillary fibre, segmentation of the medullary substance, and proliferation of the cell-elements in the nerve-sheath. The repair must be by a gradual and rather slow nutritive process.

The effect of drugs upon this process is at least problematical. Strychnine has been recommended, apparently because it acts as a violent excitant upon healthy motor-nerve cells, but why this endows it with a power to build up degenerated cells, both motor and sensory, has not been explained. Our knowledge of it is therefore empirical, and justifies its use in moderate doses. We may theorize that as an excitant to nerve tissue it excites nutrition, somewhat as a mechanical irritant will determine blood to a part, or as increased functional activity promotes structural increase. Clinical observations confirm the use of the drug. It has been used hypodermically with advantage, but I have seen ugly abscesses follow, which must be guarded against by careful antisepsis. Digitalis appears to be indicated in failing heart-power. I have used it in large doses when the pulse became feeble; but I doubt if it has the power to support a heart which is failing because of ptomaine poisoning of the nerve-elements. To do so effectually it would have to be antidotal to the noxious agent, and of this there is no evidence. I have not seen it act advantageously when cardiac collapse was sudden and marked. If digitalis acts upon the heart chiefly through the nerve-supply, as seems to be the fact, it may be that a depressed or degenerated state of these nerves in such cases hinders its proper action. Alcohol, as a more diffusible stimulant, is better than digitalis. The most important indication is to feed; or, as has been said, "to keep the bloodvessels and lymph-spaces full." There is some reason to believe that full bloodvessels are the best antidote to the infectious diseases and the best remedy for many of their sequelæ. The phosphates, especially the old formula of Parrish, are invaluable in the treatment of diphtheritic paralysis.

Electricity holds, I think, a rather uncertain position at present in the treatment of the acute degenerative paralyses which have a tendency to recover. The faradic current will not act at all upon a degenerated nerve, such as I have briefly described above; and it is worse than useless, because it deceives the patient and tends to bring reproach on a valuable therapeutic agent. And yet it is the one remedy to which the majority of laymen, and even physicians, naturally turn. It is not uncommon in the several forms of paralysis in children for the family to buy a small faradic battery, and, with the physician's encouragement, use it upon a flaccid limb which gives no response. It is a sort of talisman. To be sure, in mild cases, in which the nerve-fibres are not completely degenerated, a response may be had, but it is difficult to see how, even then, an agent which acts by such a momentary shock can advance nutrition. The same objection does not apply to galvanism, which acts upon both degenerated nerve- and muscle-fibre, and probably promotes nutrition, although we do not know just how. It is the current which should be used, but only by the physician, as, indeed, is apt to be the case, because it requires a more expensive plant, which is more difficult to use and to keep in order than the faradic machine.

In conclusion, I desire to call attention to the fact that diphtheritic paralysis can be mistaken for locomotor ataxia. As this is a grave error, especially affecting the prognosis of the case, and as it might reflect seriously upon the reputation of the practitioner, it is evident that the distinction should be emphasized more than is customary. I recently saw a case of diphtheritic paralysis in a man, in the practice of a friend, in which the resemblance to locomotor ataxia was so marked as to deceive one observer. In this case there was a history of a precedent "sore-throat." The man had numbness of the extremities, slight ataxia, abolished patellar reflexes, and some suspicious change in the pupils. The principal points of distinction were the loss of muscular power, flabby muscles, absence of fulgurant pains, ability to stand firm with closed eyes, and the history of his precedent diphtheria.

The changes in the pupils in diphtheritic paralysis are the opposite of those occurring in the "Argyle-Robertson" phenomenon of locomotor ataxia—*i. e.*, in diphtheritic paralysis the power of accommodation is lost to near objects and not the reflex to light. The onset of locomotor ataxia is more gradual than that of the other disease. In children the resemblance of the two affections is not so great, and locomotor ataxia in them is, of course, very rare, but in adults the symptoms may be confusing.

A CASE OF PORRO-CÆSAREAN OPERATION.[1]

By J. F. BALDWIN, M.D.,
of Columbus, Ohio.

Mrs. I. F. W., aged twenty-four years, weight 100 pounds, height 47½ inches. I was called to see the patient by her attending physician,

[1] Read at the meeting of the Ohio State Medical Society, June 5, 1890.

Dr. J. F. M. Heeter, July 12, 1889, and found a typically rhachitic dwarf, who was, according to her account, at about the full term of gestation. External and internal examination showed a uniformly contracted pelvis, with an antero-posterior diameter of about one and one-fourth inches. The case was manifestly one for the Cæsarean section, or some of its modifications, and it was agreed that the Porro operation was the best under the circumstances. The patient was quite intelligent, and placed herself unreservedly in our hands. Her hygienic surroundings were bad, as she lived with her husband in a cellar basement.

July 16, 10 P. M., I was called again and found her in labor. The pains were short and frequent and the os just beginning to open. Labor had commenced about five hours before. We ordered full doses of morphine, hoping thus to delay labor so as to operate by daylight. But in this we were disappointed. The pains continued to increase in frequency and severity, and by 2 A. M. of the 17th it was evident that longer delay would diminish the chances of recovery. The pains at that time recurred every three minutes, and the os was dilated to about the size of a twenty-five cent piece.

Accordingly, the operation was commenced as soon as the necessary assistants could be secured. Dr. W. H. H. Nash administered the chloroform, Dr. E. J. Wilson assisted directly, Dr. J. Leeper watched the pulse, Dr. S. L. Kistler held the rubber tube, and Dr. Heeter took charge of the infant.

The operation was performed after the method of Tait. While I had with me, for any emergency, my regular laparotomy case of instruments, I laid out: Two scalpels (one for shaving the pubes), a few hæmostatic forceps, two feet of pure rubber tubing, two knitting needles, ligatures, sponges, a drainage-tube and sutures.

As soon as the parts were cleansed and shaved an incision was made in the linea alba down to the womb, the incision being barely long enough to enable me to introduce my hand. The rubber tube looped between two fingers was then carried over the fundus and pulled down to the cervix, the fingers being carried around at this point to ascertain that no bowel had been caught. Everything then being in readiness, this tube was quickly tightened, a single hitch made, and the ends given to an assistant. The uterus was next incised, this small incision torn by the two index fingers to the full extent of the abdominal incision, a leg grasped and the child promptly delivered. Dr. Heeter at once seized the cord with compression forceps, cut it and proceeded to resuscitate the child. The placenta was then extracted through the wound, the womb lifted out of the abdomen, the rubber tube tightened and secured by a second hitch, the cervix transfixed by the knitting needles in the form of a St. Andrew's cross, and the body of the womb with the ovaries and tubes cut off. There was no hæmorrhage from the stump, but there was some from the left broad ligament, which seemed to have been cut by the pressure of the tube. This hæmorrhage was easily controlled, though, owing to the poor illumination, it caused considerable delay. The bleeding point being finally secured, the abdomen was thoroughly washed out, a drainage-tube inserted, the incision closed in the usual way, and the stump treated with perchloride of iron. There was no perceptible shock, and the patient came out from the anæsthetic nicely. There was some discharge, for a few hours, from the drainage-tube, which was removed on the second day.

Convalescence was prompt and unmarked by any special occurrences. The highest temperature was 101°. The rubber ligature came away with the slough on the thirteenth day. Her milk came in small quantity at first, but soon became ample for the support of the child. In three weeks she was permitted to be removed to a distant part of the city and the case was virtually dismissed.

The child was a female and weighed at birth seven and a half pounds. Although inheriting the peculiar deformity of the mother, it thrived very well until April 6, 1890, when it became affected with angina Ludovici, of which it died two days later.

Remarks.—The fortunate result in this case is to be attributed almost entirely to the promptness with which operative procedures were instituted. As

soon as it is determined that an operation is necessary and that the parts are in a proper condition. further delay is fraught with danger, and every hour of suffering and consequent exhaustion inflicted on the woman diminishes the chances of recovery. A very few hours of delay may suffice to turn a glorious success into a disastrous failure.

According to the statistics of Dr. R. P. Harris, of Philadelphia, this case ranks ninth among American Porro operations, and is the third successful one. It is the first in Ohio.

Tait is a strong advocate of the Porro-Cæsarean section, and under many circumstances, as when the operation has to be done at night, it is certainly the operation to be elected; but when the circumstances are favorable I regard the Sänger-Cæsarean section as preferable, for two reasons: First, because its death-rate is lower; and, second, because it does not in any way unsex the woman. But she should not be subjected to the risk of again becoming pregnant, and hence the Fallopian tubes should be ligated and cut across before the abdomen is closed.

But the Porro operation is easier of execution. Tait says it is as easy as the application of the long forceps, and hence should be selected by operators not familiar with abdominal work.

The technique of the operation, as given by Tait, is as follows:

"The first step is the abdominal incision, four inches in length, involving first the skin and then the muscles down to the sheath of the rectus, all of which ought to be divided by a sharp knife at one blow; then the tendon of one or other of the recti is opened, the muscular tendons fall aside, the posterior layer of the tendon is nipped up by two pairs of forceps and divided between them. The extraperitoneal fat is treated similarly, then the peritoneum is raised again by two pairs of forceps, a slight notch being made between them, and the moment this is effected air enters and all behind falls away. No director is required, nothing but an observant pair of eyes, lightly applied forceps, and a delicately applied, sharp-cutting knife. The finger is then introduced into the peritoneal cavity, and the relations of the uterus and bladder exactly ascertained. The peritoneum is then opened to the full extent of the four-inch incision, and the cut edges of the peritoneum are seized on each side by a pair of forceps and are pulled severally to the respective sides. No better retractors can be employed.

"The piece of India-rubber drainage tube, about eighteen inches or two feet long, is now held as a loop between the fore and middle finger of the left hand, and is by that means slipped up over the uterus and pulled down over the cervix, passing the fingers behind the cervix to see that coils of intestine are not included in it. One hitch is then made on the tubing when it has been got as far down as possible, and it is pulled as tight as is consistent with safety. The second hitch may be made in it, but what is far better an assistant keeps the tube on the strain, so that one hitch will be quite enough to effect the most efficient clamping.

"A small hole is then made in the uterus, just large enough to admit the finger. If it is possible, the position of the placenta may then be ascertained; if not, the right forefinger follows its colleague, and between the two, by gentle rending, an aperture is made in the uterus and the leg of the child is seized. The fœtus is then carefully delivered feet first, and this, despite all the authorities to the contrary, is by far the best proceeding; less blood is lost, and it requires but very gentle manipulation to release the head.

"As soon as the fœtus is removed, the placenta is sought for and removed similarly; the uterus itself, being completely contracted by this time, is then pulled out of the wound and the elastic ligature is tightened once more and finally arranged round the cervix, and the second hitch is applied. The main details of the operation are now completed; all that is required is to pass the needles through the flattened tube and through the uterus and out at the other side, forming a St. Andrew's cross, or two parallel bars, to support the weight of the uterus and the stump and keep it outside the wound. A complete toilet of the peritoneum is then made, not forgetting the anterior vesical *cul-de-sac;* stitches are passed in the ordinary way to close the wound accurately round the uterine stump.

"The uterus is now removed close down to the needles and strangulating rubber tubes, so as to leave a little tissue above. It does not do to run any risk of the ligature slipping off, though this is hardly possible after the needles have been passed carefully through the structure of the tube. A little perchloride of iron is then rubbed gently over the surface of the stump; it is dressed with dry lint and some dry cotton gauze, an ordinary obstetric wrapper is put on, and the operation is at an end. The operation really takes very much less time to perform than it takes to describe, and, as I have said before, because the details must always be the same, it is an operation in which there can never arise any unforeseen or unexpected difficulty."

In connection with this I may be allowed to state that during the last year, and in addition to this Porro operation, I made three other laparotomies.

One for adherent ovary and Fallopian tube. The parts were torn loose, but not removed. The patient made a prompt recovery, the temperature never rising above 98.6° nor the pulse above 80. Drs. Wilson, Nash, and Adams assisted me.

A second for chronic salpingitis, with retroversion and universal adhesions. The operation was exceedingly difficult, great force being required to tear up adhesions. The tubes and ovaries were removed, the uterus, which was adherent in its abnormal position, was torn loose and stitched to the anterior abdominal wall. There was free hæmorrhage, which was with difficulty controlled. Patient made an excellent recovery. I saw her about six months later and found her in robust health and the uterus in normal position.

The third case was one of uterine fibroid with general adhesions, following repeated attacks of pelvic peritonitis. The relative dangers of hysterectomy and of removal of the appendages were fully presented to the patient, and she preferred the latter operation. The operation was quite difficult owing to the adhesions, but was successful. The patient made an excellent recovery, and reports, four months after the operation, that there has been no menstruation; that she is free from attacks of pelvic inflammation, and that the tumor is perceptibly reduced in size.

I was assisted in these last two operations by Drs. Walker and Morehead, of Plainfield, Ohio, and in the last by Dr. F. F. Lawrence, of Columbus.

A CASE OF PRURITUS UNIVERSALIS PRODUCED BY THE PASSAGE OF A BOUGIE.

BY ORVILLE HORWITZ, B.S., M.D.,

DEMONSTRATOR OF SURGERY IN JEFFERSON MEDICAL COLLEGE; CHIEF OF OUTDOOR SURGICAL DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL; SURGEON TO THE PHILADELPHIA HOSPITAL, ETC., ETC.

RECENTLY a case of pruritus universalis, produced by the passage of a bougie for the cure of a lesion in the urethra, presented itself to the writer, and so far as can be ascertained it is the only case reported to the profession where the passage of an instrument has been the cause of this most distressing disease.

The writer in the course of a large experience in urethral work has seen many cases of general and local, motor, sensory and secretory neurosis dependent upon lesions of the urino-genital apparatus; but he did not believe it possible, nor did he accept it as a fact, until repeated experiments with passing a bougie produced after each operation an attack of pruritus universalis, that it was due to the instrument.

E. B., aged thirty; single; merchant. Began to masturbate at fifteen years of age and continued to do so until his eighteenth year, when he discontinued the habit and indulged in frequent sexual intercourse. This he practised three or four times a week, cohabiting twice and often four or five times a night. States that he never had any venereal disease, has not indulged in the use of intoxicating liquors, and is not a smoker.

About one year before presenting himself for treatment he began to suffer from pain in the back and nucha; later, there was burning pain on passing water, the burning sensation lasting a considerable time after each effort at micturition. He lost flesh, became morbid, irritable and restless, and sleep was unrefreshing and unsound. Heart, lungs, and urine normal.

On examination a contracted meatus and a stricture, calibre 20 F., just back of the orifice, were found. The most intense hyperæsthetic condition prevailed throughout the entire canal, especially in the prostatic portion.

The pain caused by the passage of the exploratory bougie was so intense as to produce slight epileptiform convulsions. The patient states that he had never before been similarly affected.

The meatus was enlarged and the stricture divided so as to admit the passage of a 35 F. meatus-bougie. The patient was directed to take a hot hip-bath every night before retiring; to pass a 35 F. meatus-bougie daily; to refrain from sexual intercourse, and to take sulphate of atropine, $\frac{1}{60}$ grain, with sodium bromide, 1 drachm, at bed-time.

At the end of three days he again presented himself. The burning pain after urination was much relieved; he was still suffering from pain in the back and head.

At this visit a bougie, 31 F., was passed into the bladder. Three days later the bougie was again introduced.

On the following morning an urgent message was received from the patient requesting the writer to call as soon as possible. On visiting the invalid's house he was found in bed, suffering agony from general pruritus, which had begun on the penis and scrotum and had gradually spread over the body.

To relieve the suffering every remedy recommended by the most reliable authorities was tried without any immediate benefit. Within the space of eight or ten days the pruritus gradually subsided, when a bougie was once more introduced, and the pruritus returned. A trip to Atlantic City was now recommended, and the patient remained at that resort for two weeks, when he returned, much improved in general health.

Up to this time no connection between the pruritus and the passage of the bougie had been suspected; it was presumed to be merely a coincidence. A bougie was therefore again introduced, when the terrible itching on all parts of the body returned in full force. At the end of five days, the pruritus having disappeared, the bougie was once more introduced, when the itching returned with undiminished vigor.

It now became manifest that the pruritus was entirely due to the passage of the bougie, and that the plan of treatment must be changed. A 6-per-cent. solution of cocaine was injected into the urethra, and having passed a Winternitz psychrophor, water at the temperature of 57° F. was introduced into the instrument, reducing the temperature of the water at the end of five minutes to 52° F.

A spinal ice-bag was applied to the lumbar region every night before retiring for the space of one

hour, massage used every morning, and a Turkish bath once a week. Later, after the patient began to convalesce, the following remedies were prescribed: Sulphate of quinine, sulphate of iron, of each 2 drachms; phosphate of zinc, 2 grains; sulphate of strychnine, $\frac{2}{3}$ grain: divided into 40 pills, of which 1 was taken morning and evening. Under this treatment the patient rapidly recovered. He has since married.

It would seem at first glance to be difficult to explain the sympathy that evidently existed between the irritability of the urethra and the irritability of the cutaneous surface, but reflection naturally leads to the conclusion that inflammatory lesions of the prostate gland bear the same relation to nervous affections of the male that lesions of the uterus do to allied disorders in the opposite sex.

The prostate and the structures intimately associated with it are largely supplied by nerves derived from the hypogastric plexus of the sympathetic, the several plexuses of the spinal nerves, and from the lumbar plexus through the lumbo-sacral trunk, and by reason of this free interchange of nerve fibres between the sympathetic and the cerebro-spinal system of nerves that the component parts of the genitalia are not only in intimate connection with one another, but, through the agency of the cord, with remote parts; hence it is that hyperæsthesia and inflammation of the prostate gland and its included structure, give rise not only to essential symptoms, but occasion various signs in other organs and tissues which are of a reflex or functional nature.

EARLY OPERATIONS IN PURULENT PERITONITIS.[1]

By JOSEPH PRICE, M.D.,
of Philadelphia.

In operations for purulent peritonitis, the results have been almost uniformly satisfactory. Dr. Bantock, in a late discussion, said that in opening the abdomen for these cases, he has been very much disappointed with the results. Possibly, he says, *he operated too late*, but *always* with unsatisfactory results—drainage did not seem to make any difference for *all* the patients died. Such an experience from such an operator, is a most telling argument for the early interference which he has advocated in other abdominal troubles.

No case of *general* puerperal peritonitis will recover without operation. Where there are simple inflammatory signs without localized mischief, which is the focus of the general trouble, recovery will follow general treatment. If there is pus in these cases, the necessity for early operation is as much to be recognized as in any other case or set of cases in abdominal surgery. There is but one treatment for suppurative peritonitis—section, irrigation, and drainage. Postponement is more dangerous than the operation, and at the worst only hastens a result which is certain to follow without operation.

In the *Medical Mirror*, May, 1890, is reported a case of general peritonitis, from appendicitis, in which the patient died on the thirty-first day. The results of delay are here too evident, when we take into consideration the numerous cases of appendical trouble, now relieved by prompt operation.

The late Lexington disaster, in which Colonel Goodloo lost his life, by a delay in operating of twenty-four hours, followed by another case in the same city, in which prompt intervention saved the patient, who is now active and well, is also a lesson in cases of this kind.

Further, to illustrate the subject, I introduce the following cases of my own. Other recent illustrations could easily be cited, but these are sufficient:

Case I.—Mrs. B., aged twenty-eight years. Seen five weeks after labor. High temperature; rapid pulse; rapid progressive emaciation; profound sepsis. Abdominal section revealed, thickened omenteum adherent over entire pelvis; right pyosalpinx and abscess the size of an orange in the ovary; universal adhesions; six inches of ileum cheesy and disorganized to the mucous coat along the line of adhesion on the right side. A knuckle of bowel was opened in enucleating the appendages; it was trimmed and stitched; there was purulent peritonitis, and one pint of pus free in pelvis, from leakage; appendages removed; cavity irrigated and drained; recovery.

Case II.—Mrs. M., aged twenty-four years, seen twenty one days after labor. Abdominal section showed acute puerperal pyosalpinx on the left side, and general purulent peritonitis; bowel, omentum, and pelvic organs matted together by friable adhesions; left tube gangrenous; right tube congested, but showed no evidence of pus; only the left tube removed; irrigation and drainage; recovery.

Case III.—Mrs. W., aged thirty-six; seen twelve days after labor; most profoundly septic. At the section universal friable adhesions were found; both appendages absolutely gangrenous: uterus large and soft, with cheesy walls; removal of both appendages; irrigation and drainage; recovery.

Case IV.—Mrs. F., aged twenty-three; seen four weeks after labor; removal of both appendages for left pyosalpinx and ovarian cyst; right tube occluded, adherent, and acutely inflamed; adhesions universal; general peritonitis; irrigation and drainage; recovery.

Case V.—Mrs. S., seen two years after labor. She had puerperal fever and was in bed nine months; since then has been a hopeless invalid, with loss of locomotion, constant agonizing pain, great emaciation, constant nausea and recurring attacks of peritonitis. I removed a left psyosalpinx and ovarian abscess; dense bowel adhesions; omenteum, bladder,

[1] Read before the American Medical Association, Section of Surgery, May, 1890.

and uterus glued together; irrigation and drainage; recovery from the operation and cure.

It should be noted that:

1st. All were cases of true puerperal "fever."

2d. All were saved by section, after well-directed medical treatment.

3d. The operations were undertaken to save life, not to demonstrate ideal surgical procedures.

CLINICAL MEMORANDA.

MEDICAL.

Cancer of the Pancreas and Stomach in a Woman aged Twenty.—Clara L., single, was admitted to Dr. Morris Longstreth's wards at the Pennsylvania Hospital, February 20, 1890.

For the following notes of the case I am indebted to Dr. F. B. Gummey, the resident physician:

Patient's mother died of abscess of the liver, and one uncle of phthisis contracted during the war. Her family history was otherwise negative. She had never been robust, and after a wetting, four months before her admission, menstruation ceased, and since then she has suffered greatly from pains at the epigastrium, flatulence, and constipation. The pain had been so severe as to prevent her from sleeping. It was sometimes most severe beneath the left nipple, at others, on a level with the seventh dorsal spine. At other times she had severe lancinating pain along the fifth and sixth left intercostal spaces, but it was, for the most part, worse at the epigastrium than elsewhere. There had also been progressive emaciation and loss of strength. Tongue dry and coated. Patient very anæmic. Examination of heart and lungs negative. Urine normal.

Treatment.—Calomel and soda, and milk diet.

February 24. Vomiting and flatulence relieved, but pains unabated. No tumor can be felt in the epigastric region.

March 5. Passages chalky and liver dulness apparently diminished, but there is no jaundice.

7th. Cannot retain more than an ounce of milk at a time, which is given every hour; pain radiates to the right as well as to the left hypochondriac and lumbar regions.

15th. Passages somewhat more natural after taking chopped meat and a more liberal diet.

On March 28th it was noted that she had been taking one-quarter of a grain of codeine for the relief of her pains.

On April 14th it was noted that codeine, and even morphine, in doses of one-sixth of a grain, relieved the pain only slightly. The dorsal pain was intense, patient saying "that she felt as if some one were scraping her backbone with a knife." A distinct bruit was heard over the abdominal aorta close to the cœliac axis. No thrill nor excessive pulsations could, however, be detected. The left rectus muscle very tense, and sore to the touch. Peptonized milk was ordered, but, as it induced vomiting, it was discontinued.

April 15. Ordered peptonized beef, reduced iron, and Fowler's solution, three drops three times a day, on account of the progressive anæmia. A systolic murmur was heard over the aortic cartilage.

22d. Pains unabated. At 2.15 o'clock this morning patient vomited about five ounces of blood. Up to this time she had neither vomited blood nor passed it by stool. Her pulse immediately became small and frequent, and she became dizzy, and had marked hallucinations of sight and hearing. She was given fluid extract of ergot one drachm, opium one grain, and ten minims of aromatic sulphuric acid, which she retained. Ten minutes later twenty grains of tannic acid were administered, which induced vomiting. Vomiting of blood recurred twice during the night.

While visiting the wards about noon of the following day, I was called in to see her, and found that she had another rather copious hæmorrhage from the stomach, and that her pulse was almost imperceptible. Whiskey was given hypodermically, and champagne was given by the mouth, and she soon rallied a little; her pulse returned, and she was able to swallow and to retain milk in teaspoonful doses. Enemata of peptonized milk were ordered.

23d. She was a little stronger. Nutritive enemata and hypodermic injections of whiskey and of tincture of digitalis continued. Her stomach, however, retained nothing, so the champagne was stopped.

24th. Three more hæmorrhages to-day; pulse imperceptible, somewhat delirious.

25th. Died, after a hæmorrhage, early this morning.

Autopsy showed that the head of the pancreas was firmly adherent to the greater curvature of the stomach, and presented distinct carcinomatous infiltration. In the greater curvature of the stomach, about midway between the pyloric and cardiac orifices, was a circular excavation, about three inches in diameter, the sides and floor of which showed carcinomatous infiltration. The liver was adherent to the stomach, and presented on its under surface one or two points of carcinomatous infiltration.

Henry M. Fisher, M.D.

HOSPITAL NOTES.

LUPUS AND INFLAMMATORY NODULES ON THE FACE—DIFFERENTIAL DIAGNOSIS OF A CHRONIC INFLAMMATORY NODULE FROM EPITHELIOMA—INCIPIENT SCABIES—AND OTHER CASES.

Abstract of a Clinical Lecture delivered at the New York Post-Graduate Medical School.

By ROBERT W. TAYLOR, M.D.,
PROFESSOR OF DERMATOLOGY AND SYPHILOGRAPHY.

Case I.—The first case was that of a girl, seventeen years old, with a good family history. The eruption from which she was suffering followed a mild attack of scarlet fever at the age of nine years. "Blisters" first made their appearance, and subsequently developed into abscesses of the post-cervical glands. One or two of these abscesses were treated by incision. This history, Dr. Taylor said, was not uncommon. For eight years there had been a warty incrustation at the site of the original incision on the left side of the neck. On pinching up the patch of skin situated about three

inches in front of the right ear (the "naso-labial zone"), it was found decidedly indurated and thickened; the skin was reddened, and the epithelium was shiny and cracked. This patch was oblong, and about one and a half inches long; and on its upper part were crusts composed of serum, epithelium, and sebaceous matter. The disease evidently involved the whole thickness of the skin. The lesion pointed either to a late syphilide, or to lupus; but the history, and the absence of all concomitant symptoms, excluded syphilis; while the age of the patient, and the history, pointed indisputably to lupus. Lupus, Dr. Taylor said, usually begins before puberty, either at quite an early age, or between nine and twelve years. Formerly, lupus was considered as a scrofulous trouble, but modern medicine demands a more exact nomenclature; and since the discovery of the tubercle bacillus, clinical observations have furnished some reasons for believing that lupus is a localized tuberculosis. It is reasonable to suppose that the debilitated state of the system existing after scarlet fever, especially if complicated with cervical suppurative adenitis, offered a favorable opportunity for the entrance of such bacilli into the system; and clinical experience shows that the scars or unhealed wounds left after such an adenitis are prone to degenerate into lupoid tubercles. It has been claimed by some that the tubercle bacilli have been found in lupoid nodules, but equally competent observers emphatically deny this. These discrepancies might be explained by the well-known fact that the skin is not a favorable habitat for the bacilli, and that, consequently, they are not found in this tissue in large numbers.

Treatment.—Only external remedies are indicated. The crusts should be removed, and the underlying portions well curetted under cocaine, after which an ointment, consisting of one drachm of balsam of Peru to the ounce of vaseline, should be applied. Carbolic acid ointment might be substituted for this; or, if the patient were in bed, cotton soaked with a five-per-cent. solution of carbolic acid should be applied until the inflammation subsides, when the balsam of Peru could be employed.

Case II.—The next case, a woman, thirty-three years of age, had on the tip of the nose an irregularly round, infiltrated, and ulcerated patch, which had existed for nine years, during which time she had enjoyed otherwise perfect health. The history, together with the non-destructive character of the lesion, excluded both syphilis and lupus; and the diagnosis rested between an inflammatory nodule resulting from the long-continued irritation of a pustule, and an epithelioma. The ante-auricular glands were slightly enlarged, but the cervical glands were normal.

Epithelioma, Dr. Taylor said, usually begins either as a minute crack, as a small wart, as a slight brownish discoloration of the skin, or as a small papule at the side of the nose, which bleeds freely upon irritation. The disease is sometimes of very slow growth, and exists perhaps for many years before showing its malignancy; but when this becomes manifest, the growth is found surrounded by a wall of distinctly thickened and slightly nodular tissue. In epithelioma of the face there is very slight glandular involvement. In this case there seemed to be no good grounds for believing that the lesion was more than a chronic inflammatory condition of the skin.

Treatment.—After thoroughly cleansing the part, it should be well curetted under chloroform or cocaine anæsthesia, and then irrigated with a five-per-cent. solution of carbolic acid. The subsequent process of healing should be treated on general principles; usually the balsam of Peru ointment is quite satisfactory.

Case III.—The next patient was a man who, at first, appeared to have only a few patches of thickened skin in the interdigital spaces of the right hand; but other similar patches were found along the left wrist and forearm, with a few scattered papules on the abdomen. The eruption caused much itching. The lecturer said that the case was one of incipient scabies, and still in the papular stage.

Treatment.—His bedding should be entirely renewed, and clean clothes provided. After a thorough soaking in an alkaline bath, consisting of one pound of sal-soda to thirty gallons of water at 100° F., he should receive a thorough inunction with the following ointment:

Naphthol Balsam of Peru	of each	1 drachm.
Vaseline		1 ounce.

This, in so mild a case, will probably be all that is required.

Case IV.—The next case afforded an excellent study in diagnosis. The patient, a man twenty-four years of age, had had a hard chancre five months before, and still had a cervical adenopathy, with the remains of a roseola upon the body and shoulders. On the forearms were to be seen the lesions of psoriasis which had existed as long as the patient could remember; while, by a peculiar coincidence, the outer aspect of the arm was the seat of a syphilitic papular eruption of recent development. In the absence of such a clear history, one would have been inclined to consider the entire disease psoriasis. Another point of interest was the epithelial hyperplasia found on the sides of the tongue; for a few authors claim that psoriasis occasionally affects the mucous membranes.

Treatment.—This patient should receive the usual antisyphilitic treatment by baths and inunctions.

Case V.—Another manifestation of syphilis, alopecia, next received attention. The man, thirty years old, was in the fifth month of his syphilis. The spots of alopecia were quite small, and did not present the shiny appearance of alopecia areata. There were papules and pigmented patches on the hands; round, ulcerated, and exfoliated patches upon the tongue; the throat was filled with ulcers, and the tonsils were much enlarged.

Treatment.—The patient was cautioned about conveying contagion by means of cups, tobacco-pipes, and similar utensils, and directed to spray and gargle the throat frequently. In severe cases of syphilitic sore-throat in hospital, Dr. Taylor directs the patient to gargle for fifteen minutes with a drachm of table salt to a tumbler of water, as hot as can be tolerated, and then to use the following strong gargle:

Bichloride of mercury	8 grains.
Tincture of myrrh	½ ounce.
Water	8 ounces.

When the ulcerative process begins to subside, the quantity of bichloride should be gradually reduced. The patches on the hands should be rubbed every night with mercurial ointment, and gloves worn during the night.

Case VI.—Another patient, a Chinaman, forty-seven years old, who had had a chancre four years before, and had been pretty thoroughly medicated with the mixed treatment, presented himself with a non-ulcerating tubercular syphilide on the left side of the neck, showing decided thickening of the skin, and extending at the periphery in an irregular manner. This lesion belonged to the tertiary period.

Treatment.—Dr. Taylor directed the continued application of mercurial ointment, with frictions of the part, and the administration of the following:

Biniodide of mercury . . .	3 grains.
Potassium iodide	6 drachms.
Comp. tinct. of cinchona . . .	4 ounces.

One teaspoonful three times, increasing to four or five times, daily.

Case VII.—A young woman was then shown with condylomata near the anus, which, if not treated, would extend and lead to ulceration, fissure, and stricture of the rectum.

Treatment.—The treatment should consist in the judicious use of mercury, if possible by inunction, and the careful washing of the patches with carbolic soap, followed by dusting with calomel and the application of cotton.

MEDICAL PROGRESS.

The Administration of Creasote in Phthisis.—From observations made on seventy-three cases of phthisis treated with creasote, Dr. William H. Flint (*New York Medical Journal*, July 26, 1890) draws the following conclusions:

1. That intrapulmonary and intratracheal injections of creasote are of doubtful utility, and may be positively injurious.

2. That, for administration by mouth or rectum, solutions and emulsions of creasote are preferable in most cases to capsules, pills, or wafers.

3. That milk is an excellent vehicle for the administration of creasote in solution or in emulsion.

4. That each method of administering creasote used by the author—viz., by inhalation, by mouth or rectum alone, and by both the latter channels simultaneously—is useful, and may each be particularly adapted to individual cases. In suitable cases the most rapid progress seems to be made when all these methods are utilized.

5. That the best results for each individual attend the administration of the maximum quantity of creasote which this patient will bear.

6. That the average patient will not easily tolerate more than ten to fifteen minims of creasote *per diem* for any great length of time, and that many will only bear two or three drops *per diem*, continuously administered.

7. That it is very important that the treatment be uniform and uninterrupted.

8. That, consequently, an effort should always be made, if intolerance of creasote is shown by any one mucous surface, to employ some other channel of introduction, in order that the continuity of the treatment be not interrupted.

The solution used by Dr. Flint for inhalation was composed of equal parts of creasote, alcohol, and chloroform. The inhalers used were Dr. Robinson's and that of the Brompton Hospital. In mild cases the inhalations were given for fifteen minutes, every two or three hours, in severe cases every hour during the day, and every three hours during the night. Internally he at first used Jaccoud's mixture (creasote, 6 minims; glycerin, 1 ounce; whiskey, 2 ounces), but found that the creasote could not be given in large dose without administering at the same time more whiskey than, in many cases, was desirable. In some cases, too, it was not well borne. For these reasons he finally adopted an emulsion of cod-liver oil, 40 parts; mucilage of acacia, 60 parts; with 2 minims of creasote to each drachm. This was well tolerated, especially if given after food. In suitable cases the emulsion was given every two hours and increased up to the point of toleration. To patients who could be persuaded to adopt temporarily an exclusive milk diet the creasote emulsion was administered in the milk, being thoroughly mixed with the latter by energetic shaking. Dr. Flint succeeded in giving more creasote in this manner without exciting gastric disturbances than by any other method. In several cases twenty-four minims of creasote were daily given for several consecutive days.

Iodoform-emulsion in the Treatment of Tuberculous Joints and Cold Abscesses.—At the recent meeting of the German Surgical Association (*Centralblatt f. Chirurgie*, June 21, 1890), Bruns of Tübingen, and Krause of Halle, reported their results in the treatment of tuberculous joints and cold abscesses by means of injections of mixtures containing iodoform. Bruns uses a sterilized mixture containing 1 part of iodoform to from 10 to 20 of olive oil or glycerin, which is injected into the abscess cavity after the pus is evacuated. The operation may be repeated, if necessary, and usually within a few weeks or months the abscess diminishes, and finally disappears. Bruns has treated in this manner over 100 cold abscesses, among them 10 cases of psoas abscess, with 80 per cent. of cures. He has also used the method in the treatment of tubercular pleuritis, and in 50 cases of tubercular joint-disease, with surprisingly good results, even in cases of long duration. If there are fungoid, tuberculous granulations in or around the joint he inserts a hollow needle, breaks them up and injects in one or more places from 30 minims to 1½ drachms of the emulsion. If there is an abscess, the pus is withdrawn and the cavity filled with the emulsion.

Nearly all the surgeons who discussed this paper were in accord with the author. Trendelenburg said that he had treated 135 cases in this manner. Von Eiselsberg said that Billroth had practised the method with satisfaction in the treatment of cold abscesses and other tubercular diseases since 1881.

Krause reported 60 cases of joint disease treated by injecting a 10-per-cent. emulsion of iodoform in glycerin, or a mixture of iodoform in water of the same

strength. In 36 cases of knee-joint disease there were 15 cures, in 15 of hip-joint disease 4 cures, in 6 of disease in the tarsus 1 was cured, and in 5 of disease in the joints of the hand 3 were cured. All of these cases were far advanced when the treatment was commenced. If there are abscesses around the joint, Krause evacuates them and washes out the cavities with boric acid solution before injecting the iodoform. The injections are made every two, three, or four weeks, according to the severity of the case.

Extemporized Surgical Gauzes. — HELBING gives the following recipe for the rapid preparation of surgical gauzes: Select a good material, free from oily matter, weighing about ten drachms per square yard, and having not less than thirty threads, running each way, in the square inch. Weigh out as much of the gauze as is required, and take a corresponding weight of the antiseptic. The material should be saturated with ether or with a mixture of ether and alcohol, in which the antiseptic has been dissolved, one ounce of the gauze requiring thirty ounces of solution. The gauze is wrung out several times and resaturated. In drying the gauze, it should simply be unfolded and shaken a few times. All the different gauzes may, in this manner, be prepared, as carbolic acid, corrosive sublimate, eucalyptol, iodoform, or thymol.—*Pharmaceutical Era*, June, 1890.

Injection of Filtered Air in the Diagnosis of Ruptured Bladder. — PROFESSOR KEEN suggests the following method (*Annals of Surgery*, July, 1890), which he has not yet used in practice, of determining the presence of a rupture of the bladder:

1. Introduce the catheter and empty the bladder of any urine that may be present.

2. Connect the catheter with an ordinary Davidson's syringe. This should have been disinfected. Over the distal end of the syringe a moderately large mass of absorbent cotton is tied. If the operator prefers, he can connect the distal end by a rubber tube, which has been padded with absorbent cotton, which may itself have been made antiseptic. The cotton in either case acts as a bar to the entrance of germs, as in the tubes of bacteriologists. Air is then pumped into the bladder. Should no rupture have occurred, the rounded, elastic, tympanitic bladder will appear in the hypogastrium. Should there be a rupture, the air will escape through the rent into the general peritoneal cavity, and distend the entire belly. It is, perhaps, even a needless precaution to have the air free from germs in carrying out this procedure, for, should the bladder be ruptured, laparotomy, of course, would be done, and the unfiltered air of the room would gain free access to the peritoneal cavity from the abdominal wound. If the bladder is not ruptured, the air pumped in would, of course, escape at once by the catheter, and have done no harm; but it would be better to filter the air, and so exclude any possibility of infection.

Ear Reflexes.—DOWNIE (*Archiv f. Kinderheilkunde*) describes various reflexes having their origin in the ear, which are familiar to otologists, but, perhaps, not so well known by general practitioners. Cough, this writer says, may be excited by introducing unwarmed specula into the meatus, and may also be produced by inspissated cerumen, especially if the mass is loose and changes its position during the movements of the lower jaw. This cough is often falsely called "stomach cough." Foreign bodies in the ear may produce similar phenomena. The author reports an example in which a phthisis-like cough with pulmonary symptoms disappeared after removing a plug of cerumen. Irritation of the external canal may cause gastric reflexes, such as vomiting. Aural polypi, as well as cerumen plugs, may excite irregular cardiac action, which rapidly disappears after removing the local trouble. Epileptiform convulsions may be due to the same causes, in proof of which the author cites a series of cases observed by himself.—*Archives of Gynæcology and Pædiatry*, July, 1890.

Violet Mouth-wash.—The following is said to be an excellent mouth-wash:

R.—Tincture of benzoin	. .	7 parts.
" " rhatany	. .	30 "
" " myrrh	. .	60 "
" " orris root	. .	500 "
Rose water	. . . .	250 "
Alcohol	. . . .	250 " —M.

—*American Practitioner and News.*

Treatment of Anal Fissure.—*L'Union Médicale* for June 28th gives the following formula for the treatment of anal fissure;

Boric acid	. . . . . 45 grains.
Hydrochlorate of cocaine	. . 15 grains.
Lanolin	. . . . . 1 ounce.

This is to be made into an ointment and applied to the fissure, after which the spot is to be touched with a solid stick of silver nitrate.

Lactic Acid Treatment of Diarrhœa. — HAYEM has recently reported before the *Société Médicale des Hôpitaux* the success which has attended his employment of lactic acid in diarrhœa. He prescribes the acid in the dose of 2 drachms in the form of a lemonade, made as follows:

Lactic acid	. . . . . 2 drachms.
Simple syrup	. . . . . ½ ounce.
Water	. . . . . 3 ounces.

To be drunk during the intervals between meals.

HAYEM thinks this particularly useful for the diarrhœa of typhoid fever, and in that form of lientery dependent upon *hypo*-acidity of the stomach. The same observer also recommends it as a cure, and prophylactic in epidemic cholera.—*L'Union Médicale*, June 28, 1890.

Salve for Alopecia.—MORWIN recommends, in *L'Union Médicale* for June 28, 1890, the following salve for alopecia:

Gallic acid	. . . . . 45 grains.
Essence of lavender	. . . 15 drops.
Vaseline	. . . . . 1½ ounces.
Castor oil	. . . . . 6 drachms.

This is to be well rubbed in at night over the part affected.

SATURDAY, AUGUST 9, 1890.

THE TENTH INTERNATIONAL MEDICAL CONGRESS.

Recognizing the interest which every member of the profession must feel in the proceedings of the Tenth International Medical Congress, now holding its meetings in Berlin, The Medical News presents in this issue two of the most important papers read by Americans, and also a detailed account by cable of the meetings of August 4th, 5th, and 6th. The paper by Dr. Wood not only possesses a value of its own, but a peculiar interest in that it was the only address delivered before this representative body of medical men as the contribution of American medicine to the general fund of knowledge, while that of Dr. Billings is noteworthy because of its scientific bearing upon questions which are of peculiar interest to the Germans, and to all countries forced to maintain large armies.

The use of the cable also places in the hands of each reader of The News a report of the three most important days of the meeting almost before the Americans who attended the Congress have had time to digest the information to which they listened; and in the issue of August 16th we hope to present the proceedings of the closing days of the meeting in an equally readable form.

PERFORATION OF TYPHOID ULCERS.

In the treatment of typhoid fever no danger is so much dreaded as hæmorrhage from the ulceration of a bloodvessel in a Peyer's patch, or the collapse which is sure to follow perforation of the intestine through the same morbid process. Everyone who has seen much of typhoid fever must have met with cases in which during advanced convalescence or in a mild period of the attack one of the accidents named above has occurred, and has felt that at last the case had been taken entirely beyond his control and that the patient was doomed almost without a single hope. Very recently before the Association of American Physicians, at their meeting in Washington, Dr. James E. Reeves, of Chattanooga, expressed the belief that he had seen recovery take place after perforation had occurred in enteric fever, and although others of wide experience, notably Dr. Loomis, of New York, expressed a doubt if any such cases were *bona fide* perforations, and if recovery ever followed perforation, several instances confirming the assertions of Dr. Reeves have been recently reported.

In the *Deutsche medicinische Wochenschrift* of December 26, 1889, Dr. Reuneri reports three cases, all occurring in women under forty-eight years, in which during the course of enteric fever all the classical symptoms of perforation occurred, such as collapse, violent pain in the belly, and a rapid, feeble pulse, with a great fall of bodily temperature. The vomiting was incessant, and palpation revealed a swelling in the right iliac fossa of considerable size, while constipation was present. In all these instances opium, small pieces of ice taken by the mouth, and the general measures devoted to the treatment of peritonitis occurring in a feeble subject were resorted to, and recovery ultimately occurred, the patients, after some weeks of convalescence, leaving the hospital entirely well. It would appear, therefore, that perforation of the intestine in typhoid fever is not necessarily fatal, although the vast majority of cases do not survive the accident.

Aside from the question which we have just been considering, another point of interest, of a surgical character, is not to be overlooked. Already surgeons have reduced the mortality of intestinal perforations arising from traumatic causes to a very low percentage, and a few of them have been bold enough to attempt such measures in the perforations we are considering. Although the results reached

in most instances have not been encouraging, in certain picked cases we believe an operation to be perfectly justifiable, and, if the accident occurs during advanced convalescence from indiscretions in diet, to be absolutely indicated. Indicated, because the escape of pieces of hard food into the abdominal cavity places the patient beyond all hope of recovery, and because his physical state at such a time is sufficiently good to give a skilful surgeon at least a chance of saving the patient's life.

THE RECENT ELECTRICAL EXECUTION.

THE revolting details of the recent electrical execution have been so fully reported in the newspapers that more than an allusion to them in our columns is unnecessary. The results of this, the first execution under the guidance of science, will give the opponents of the method a powerful weapon, and, we fear, it is not improbable that the law requiring the execution of condemned murderers by electricity will be in consequence repealed. The enemies of capital punishment, too, will use the reports to endeavor to prove that no form of execution can be painless, and that the maximum penalty for murder should be imprisonment for life. From the daily papers we learn that our esteemed contemporary, the *Medical Record*, will editorially take this opportunity of denouncing all forms of capital punishment.

It must be remembered that the entire proceeding was in the nature of an experiment; that those in charge were nervous and apprehensive of failure, and thereby incapable of carrying out the verdict of the court with proper precision. Furthermore, it is probable that after the first shock the contortions of the victim were as painless as the legendary spasms of the frog's legs on Volta's copper railing.

Sickening and revolting as the spectacle was, there is reason to believe that the death was less painful than is ordinarily that by hanging, after which muscular spasms often continue for many minutes. It has been claimed by the opponents of electrical execution that this method of punishment is brutal, but the measure of brutality should be the suffering of the victim, and no proof is available that death was not painless in this instance. We believe that the death penalty should be effected by electricity. Hanging has become so familiar to us that its brutality is forgotten. We forget that many a man on the gallows dies from *slow* asphyxia—than which probably no form of death is more horrible. Electricity is a substitute not only better from the standpoint of simple humanity, but, as shown by Professor J. William White in a letter to this journal (April 26, 1890), is more likely to prevent crime. Dr. White's belief is that the criminal classes are influenced more by the probability of conviction than by the severity of the punishment, and that the number of convictions increases in direct proportion to the mildness of the penalty. The New York Commission to Investigate the Most Humane and Practical Method of Carrying into Effect the Sentence of Death reached the same conclusion, and reported that "any undue or peculiar severity in the mode of inflicting the death penalty neither operates to lessen the occurrence of the offence, nor to produce a deterrent effect."

It is, therefore, clearly evident that upon other grounds than pure humanitarianism capital punishment should be as painless as it can be made.

That electricity can be so applied as to cause instant and painless death no one can doubt who reads of the too frequent fatal accidents with broken "live wires."

One object of the new law, and a laudable one, is to limit the publication of the details of an execution to a simple statement of absolute fact. This has been entirely ignored—horrible, disgusting, and exaggerated descriptions were spread broadcast, descriptions that no one can read without a sense of degradation. For this publicity unfaithful servants of the law and the reportorial desire for the sensational are responsible.

It is greatly to be hoped from the standpoints of humanity, and for the checking of crime, that the State of New York will not hastily abandon the advanced position she has assumed in this matter, and equally desirable that before a second execution by electricity takes place, competent and cool-headed officials will be selected to carry into effect the verdict of the law.

The autopsy showed that the changes in the floor of the fourth ventricle were sufficient to cause death, and it cannot be doubted that death would have taken place without delay but for the too early order to stop the current. The misfitting of the head electrode was no worse than the misplacing or slipping of the hangman's noose, and the slight burning of the body of no more moment than the awful parchment-like blue line of the rope with the exophthalmic eye and swollen face.

(By Cable.)

SPECIAL CORRESPONDENCE.

INTERNATIONAL MEDICAL CONGRESS.

Tenth Annual Session.
Held at Berlin, August 4th–9th, 1890.

(From our own Correspondent.)

The International Medical Congress was called to order in the Circus Renz, on Monday morning, August 4th, by the President, Professor Virchow. The beautifully decorated hall held 5000 representatives from all parts of the world, to whom Professor Virchow extended a most hearty welcome. In his opening address he called attention to the great advances in medicine, and to the value of international meetings in uniting the medical world in the struggle against disease and death. He further said that the object of medical associations should not be to get more pay or shorter hours, but to increase our ability for research, and to diminish the dangers that surround humanity. He expressed the Emperor's sympathy with the objects of the Congress, and said that Germany would devote herself to science and humane efforts.

Secretary Lassar reported that 5000 delegates were present, 2500 of whom were foreigners. Of all countries the United States takes the lead, with 500 delegates. England follows with 300. It was announced that there were 700 papers to be read in the three official languages, namely, English, German and French. This report was followed by addresses of welcome by Herr von Boettscher, German Minister of Education, and the representative of the Chancellor; Herr von Gossler, Prussian Minister of Ecclesiastical Affairs; Herr von Fordensbeck, the Mayor of Berlin, and by Dr. Graf, President of the German Medical Association. On behalf of the American delegation, Surgeon-General Hamilton thanked the Germans for their great hospitality; Sir James Paget tendered the thanks of the English delegates, Dr. Bouchard those of the French, and Dr. Bacelli then spoke for Italy, in a delightful Latin oration, that charmed the hearers and demonstrated that the dead language united all scientists. Tremendous applause proved how well the oration was appreciated.

The following Honorary Presidents were then announced: From the United States, John S. Billings, M.D.; Austria, Professor Billroth; England, Dr. Stokes; France, Professor Bouchard; Italy, Dr. Bacelli; Germany, Carl Theodore, Duke of Bavaria, who, though of royal blood, is a distinguished surgeon. Professor Virchow was made the permanent President and Dr. Lassar, the permanent Secretary.

Sir Joseph Lister then read a paper entitled "The Present Position of Antiseptic Surgery," in which he referred to Metschikoff's brilliant experiments in regard to the destruction of bacteria by the amœboid cells of living tissue, and showed how small particles of septic material are destroyed by leucocytes. He said that the work of Tait and Bantock is not opposed to the principles of antisepsis, but, on the contrary, that their cleanliness, and care in the preparation of instruments, sponges, and dressings show how well they follow the laws of antisepsis.

He believed in the use of strong antiseptic washes in all surgery except that of the peritoneum, where we should use solutions not stronger than 1 to 10,000, and in synovial membranes, where 1-to-4000 solutions are proper. The spray, he said, has no real value, and he hopes that the day may come when we will need little irrigation and no drainage. Floating particles in ordinary air, he thinks, can be disregarded. He recommended the double-cyanide gauze as the best dressing.

Dr. Robert Koch, the famous discoverer of the tubercle and cholera bacillus, followed with a paper on "The Present Status of Bacteriological Science." He thinks that the future will give us fixed ideas of the etiology of all infectious diseases, be they bacterial or not. He believes that species of bacteria are fixed and that one form cannot develop into another. In bacterial examinations he said that we must never depend on one characteristic, but should exhaustively test all the qualities. He described a new bacillus, very similar to that of tuberculosis, but showing slight differences, and though it had puzzled the author of the paper, it is now established that this new form is a distinct species which causes chicken tuberculosis. It seems now that the exanthemata are not due to bacteria, but, perhaps, to some organism similar to the plasmodium malariæ; but long and patient work and culture experiments must decide this point. The results of bacteriology are comparatively slight so far, but if the apparent results of his present work are true, bacteriology will be a greater science in the future. He has a new remedy by which he can check tuberculosis in the guinea pig, and can prevent even inoculations from affecting the animal; he did not say, however, what the remedy is.

Tuesday was devoted to the work of the sections. In the section of Internal Medicine the treatment of chronic nephitis was the main theme. An absolute milk diet and the administration of little medicine seemed to be in the opinion of all present the proper treatment.

The treatment of tubercular peritonitis by laparotomy was discussed very fully. No one seemed to have a clear idea of how a cure takes place after abdominal section, although according to the re-

ports cure results in 30 to 60 per cent. of the cases. It was therefore thought that laparotomy is the best therapy if a diagnosis can be positively established. In the acute miliary form operation was, of course, considered of little value.

Terillon reported his results in resection of the stomach and intestine for carcinoma. His present position is that although so far no operation has resulted in preventing a recurrence of carcinoma, the patient's comfort is so much increased and his days so much lengthened that it is our duty to give him the benefit of an operation.

At the second general session, Sir James Paget and Dr. John S. Billings presiding, it was decided to hold the next meeting of the Congress at Rome. The official records show an attendance of 5561 members. Of these there are 623 Americans, 421 Russians, 353 English, and 171 French.

Professor Bouchard, of Paris, then spoke for two hours on the "Mechanism of Infection and Immunity, and was followed by Axel Key, of Stockholm, on The "Relation of Puberty to the Diseases of School Children." Key has found that the year of greatest growth in boys is the seventeenth; in girls the fourteenth. While girls reach full height in their fifteenth year they acquire full weight at the age of twenty. Boys are stronger than girls from birth to the eleventh year; then girls become superior physically to the seventeenth year, when the tables are again turned and remain so. He stated that from November to April children grow very little and gain no weight; that from April to July they gain in height but lose in weight, and that from July to November they increase greatly in weight but not in height. These are the result of over 6000 observations. During the school months children suffer far more from disease than in the vacation, and during school years far more than before or after. Key thinks that usually school work is far too hard in the lower classes and that the children do not get sufficient muscular strength. Less school work and more physical training until the twelfth year are necessary to make our coming generation strong; and a child should not undergo any severe mental labor.

There is a splendid exhibition of medical and surgical appliances, in which all nations are represented. The place of the special sessions is the famous Art Exposition buildings, and no International Congress ever met in more beautiful quarters. The arrangements are perfect, and one hears nothing but praise from all foreigners. Very differently were the Americans treated who attended the British Medical Association, in Birmingham — over fifty withdrew their credentials on the second day, and nearly every American member resigned. The Americans are intensely indignant, especially so at Mr. Lawson Tait. Further details concerning the action of these delegates will be sent in time for your next issue. Tuesday evening the city of Berlin gave a magnificent banquet to the foreigners in the city hall, and Wednesday evening there were banquets by the different sections. The delightful weather adds not a little to the enjoyment of the meeting.

CORRESPONDENCE.

LONDON.

Nurses and Nursing. Operative Treatment of Pyæmia following Ear-disease. Legislation for Infant Life Insurance. The Amended Scheme for the new University of London.

Nurses and nursing have lately been much discussed. A few days ago the National Pension Fund for Nurses was formally inaugurated by a most successful gathering under the direct patronage of the Princess of Wales, when about a thousand nurses who have already enrolled themselves as members were present. The institution has made a most excellent start, a sum of something like £70,000 having been already accumulated, largely owing to the munificence of four donors of £10,000 each. Started almost contemporaneously with this is the Jubilee Institute for Nurses, which also has the advantage and benefit of royal patronage, for the Queen has graciously handed over the money received from the women of England in commemoration of her jubilee to found an institution for supplying trained nurses to the sick poor in their own homes. A very representative committee has been appointed to carry the scheme into effect, the medical element on it being Sir James Paget and Sir Dyce Duckworth, whilst at least two of the ladies on the council have had some years' practical experience in nursing. For several years past a private association has been carrying on work of this kind as successfully as its limited means would permit, so that the new undertaking starts with every prospect of a career of great usefulness and success. The profession of sick-nursing has become so popular in late years that almost all the leading hospitals have started nursing homes, and advertise their willingness to send out nurses to private cases. The fact is that this is a very satisfactory way of making money, as from one to two guineas a week are charged, which, of course, leaves a good margin for profit. Of course, the thing will soon be overdone, and there are indications that before long the market will be overstocked, but we have not yet quite reached that point.

In a former communication I alluded to Mr. Arbuthnot Lane's work on the subject of pyæmia consecutive to ear-disease and thrombosis of the lateral sinus. He has followed up his former paper with a note on pyæmia from otitis without thrombosis of the lateral sinus, and apparently his remedy is to ligature the internal jugular vein and occlude the sinus. He does not give the line of reasoning which led him to adopt the treatment, but it appears to have been successful. His patient was a child of three years, admitted for a left otorrhœa of three weeks' duration, and facial paralysis of that side for about the

same length of time. A week before the patient came under observation the discharge ceased, the mastoid area became tender, and he had a rigor every day. On admisssion to the hospital there was a fluctuating swelling over the mastoid, some discharge from the meatus and facial paralysis; there was no optic neuritis. His temperature was 104°. Under an anæsthetic the mastoid antrum, which was distended with pus, was obliterated by levelling down its edges, and the middle ear was freely opened, so that the dura of the middle fossa was exposed. It was thickened and inflamed, but there was no pus on it. On the evening of the following day he had a rigor, and the next morning the dura of the posterior fossa was fully exposed, and a collection of pus discovered between the lateral sinus and adjacent dura and temporal bone. Though the wall of the sinus was soft and doughy, there was no evidence of thrombosis. The child had a rigor that day and on the following day, and Mr. Lane then determined to ligature the internal jugular vein, and to open and plug the lateral sinus. The vein was thereupon ligatured, but the child became so collapsed that the subsequent steps of the operation were deferred. On the following day he had a rigor, and on the succeeding day Mr. Lane reopened the wound, and found that the sinus was firm, having evidently quite recently undergone thrombosis. From this time up to the date of the report, sixteen days later, the child did well, and his condition was, in all respects, satisfactory. Mr. Lane is certainly to be congratulated, for in the hands of a less courageous operator it is more than likely that the disease would have run its usual course to a fatal termination.

Two schemes are at present before the Legislature with a view to the better protection of infant life. That which is though to have the most chance of becoming law is the one introduced into the House of Commons, which makes more stringent regulations respecting baby-farming. The other is the bill of the Bishop of Peterborough introduced into the House of Lords, and at present passing through the ordeal of a preliminary committee. The bishop, who is certainly one of the greatest orators of the day, did not mince matters when introducing his bill, and did not hesitate to say that children were killed for the sake of the insurance money notwithstanding all the supposed safeguards of a medical certificate of the cause of death, or even a coroner's inquest. His proposals strike at the root of the whole matter, and, in my opinion, no scheme will be efficacious which does not follow pretty closely the lines he has laid down. The pith of his proposal is that the parents shall not directly or indirectly receive any money on account of the death of a child; they may insure its life as at present, but the amount insured shall be paid solely to the undertaker, and shall not exceed that necessary for the funeral expenses. It is rumored that there is very little chance of such a bill getting through the House of Commons, but I am quite sure that nothing else will really check the present great and growing evil.

The University of London, or rather the senate of that university, have promulgated their revised scheme for the re-constitution of the university, and it seems to be meeting with considerable support. University and King's Colleges have already accepted it, and it remains to be seen what the College of Physicians and Surgeons will do. Whatever they do must be done jointly. On the whole, the scheme seems to be as favorable to them as anything they are likely to get in any other way, for it provides that they shall conduct the examinations in conjunction with the university, but it is not made clear in what way the new examination is going to be more accessible than the old one. Two great causes of complaint against the existing scheme are the severity of the preliminary examination in scientific subjects, and the fact that a man cannot count any medical study toward his degree till he has passed this examination. These two facts do not seem to be in any way remedied, so I doubt very much whether the student will really be much better off. The scheme has not, however, yet been approved by all parties concerned.

NEWS ITEMS.

The Nova Scotia Medical Society.—The twenty-second annual meeting of the Nova Scotia Medical Society was held July 2d, 3d, and 4th, at Granville Ferry, Annapolis County. The following officers were elected for the ensuing year: Dr. J. A. Coleman, of Granville Ferry, President; Drs. Stephen Dodge, of Halifax, and G. E. Buckley, of Guysboro, Vice-presidents; Dr. W. S. Muir, of Truro, Secretary and Treasurer. Delegates were chosen to meet delegates from the New Brunswick and Prince Edward Island associations, with a view to a union of forces under the guise of a Tri-provincial or Maritime Medical Association. If such a union is effected, the membership will be not far from six hundred.

Mississippi Valley Medical Association.—The Mississippi Valley Medical Association will hold its sixteenth annual session at Liederkranz Hall, Louisville, Kentucky, October 8, 9, and 10, 1890. The medical profession is cordially invited to attend. Papers are solicited, the titles of which should be sent to the Secretary, Dr. E. S. McKee, 57 W. Seventh Street, Cincinnati, as soon as possible. The social arrangements are to be in keeping with Kentucky's well-known hospitality. The programme is already assuming proportions of magnitude and interest, and is still growing. The annual meeting of the American Rhinological Association will be held at the same place, October 6, 7, and 8, 1890. The Secetary, Dr. R. S. Knode, National Bank Building, Omaha, Nebraska, will receive titles to papers. Dr. John A. Wyeth, of New York, and Dr. Frank Woodbury, of Philadelphia, have consented to read papers.

Medical Missions.—At a recent meeting in London the subject of medical missions was discussed. One of the speakers, a veteran official from India, stated that among the Asiatics no mission can be regarded as fully equipped unless it has a medical department. Medical skill is extremely important as a pioneer influence, and a physician will be able to establish a mission where others would fail to obtain a footing. The Indian government highly appreciates the work that has been done by the medical men who have gone among the wild tribes along the northern frontiers. Traders know of all these posts, and frequently travel a long distance to obtain medical assistance. In January, 1879, a very warlike tribe on the frontier made a raid on Tonk, which is in

British territory. The place was sacked and burned; but the hospital and the house of the medical missionary were spared, because half of the patients that had been treated there were members of the attacking tribe.

An Aboriginal Method of Preventing Over-population.—An editorial in the *Weekly Medical Review* describes the following curious method of preventing over-population as practised by the aborigines of Australia. The method, called the "mika" operation, consists in making an incision into the urethra, near the scrotum, with a flint knife, cauterizing the wound with hot stones, and inserting wooden pegs to prevent closure during cicatrization. In some tribes it is said that all but about five per cent. of the male children are compelled to undergo the operation. In other tribes the operation is postponed until just before marriage.

Medico-Chirurgical College.—W. C. Hollopeter, M.D., has been elected Lecturer on Diseases of Children; and Ernest B. Sangree, M.D., Director of the Histological Laboratory.

The Climax of Quackery.—An infamous example of quackery was recently brought to light in Milwaukee, in the prosecution of the "Gun Wa Medical Company." The supporters of this fraud have branches in several cities, in which they advertise that they have an eminent Chinese physician, Gun Wa, who is versed in the medical lore of the Oriental schools, and who has a remedy for every disease to which flesh is heir. This "physician" is generally some ignorant laundryman, who knows too little English to be able to communicate with those who would consult him. He therefore has an interpreter—in Milwaukee this was "Doctor" Jansen—and this "interpreter" does not know a word of Chinese. During the active operations of this swindle in Milwaukee, this alleged famous Chinese physician, Gun Wa, was personated by three different laundrymen. It is not easy to conceive of a more barefaced and impudent imposture than this, which has been practised with considerable success in several Western cities.

A Summer Camp for Boys.—On the southern border of Lake Asquam, in New Hampshire, midway between Centre Harbor and Plymouth, is a camp for boys who require out-door life. The camp is on high and dry ground, with fine views of lakes and mountains. The exercises embrace boating, swimming, tours of exploration, base ball, tennis, and other summer sports, always under competent supervision. The physical needs of each boy are studied, with a view to instruct him in the proper manner of breathing, walking, running, jumping, and other forms of athletics in his critical formative period. The plan was originated by Mr. William T. Talbot, of Boston.

The Medical Department of the University of New York.—The Medical Department of the University of New York has just issued its semi-centennial catalogue; an interesting pamphlet, well illustrated with photogravures of all the new laboratory improvements. Our medical college annual announcements are too often not at all descriptive of their respective institutions, and this is a welcome departure from the old rule.

The New York Hospital Sunday Fund.—The collections on behalf of this fund in New York City, in 1889-'90, amount to $57,079, being the largest yet received. In the previous year the fund received $52,039; while in 1879, the year of the first collections, the receipts were $24,465.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 29 TO AUGUST 4, 1890.

With the approval of the Acting Secretary of War, leave of absence for ten days is granted CURTIS E. PRICE, *Captain and Assistant Surgeon.*—Par. 3, *S. O. 175, A. G. O., Washington, D. C.*, July 29, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 2, 1890.

BLACKWOOD, N. J., *Assistant Surgeon.*—Ordered to duty in the Bureau of Medicine and Surgery.

WALES, P. S., *Medical Director.*—Ordered to duty in charge of the Museum of Hygiene.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM JULY 5 TO JULY 26, 1890.

BAILHACHE, P. H., *Surgeon.*—Granted leave of absence for seven days, July 26, 1890.

HUTTON, W. H. H., *Surgeon.*—To proceed to Chicago, Ill., on special duty, July 24, 1890.

GODFREY, JOHN, *Surgeon.*—Granted leave of absence for thirty days, July 21, 1890.

PECKHAM, C. T., *Passed Assistant Surgeon.*—When relieved at Memphis, Tenn., to proceed to St. Louis, Mo., and assume command of the Service, July 9, 1890

DEVAN, S. C., *Passed Assistant Surgeon.*—Granted leave of absence for twenty-five days, July 15, 1890.

KALLOCH, P. C., *Passed Assistant Surgeon.*—Orders of July 5th, to St. Louis, Mo., revoked July 8, 1890.

WILLIAMS, L. L., *Passed Assistant Surgeon.*—Relieved from duty at Baltimore, Md., and to assume command of Service at Memphis, Tenn., July 8, 1890.

PERRY, T. B., *Assistant Surgeon.*—To proceed to Baltimore, Md., for temporary duty, July 17, 1890.

STONER, J. B., *Assistant Surgeon.*—Granted leave of absence for thirty days, July 21, 1890.

HUSSEY, S. H., *Assistant Surgeon.*—To proceed to Pittsburg, Pa., for temporary duty, July 18, 1890.

YOUNG, G. B., *Assistant Surgeon.*—Granted leave of absence for fifteen days, on account of sickness, July 12, 1890.

STIMPSON, W. G., *Assistant Surgeon.*—To proceed to Buffalo, N. Y., for temporary duty, July 12, 1890.

HOUGHTON, E. R., *Assistant Surgeon.*—To report to the medical officer in command New York Marine Hospital, for temporary duty, July 14, 1890.

PROMOTION.

MAGRUDER, G. M., *Passed Assistant Surgeon.*—To rank as such from July 12, 1890.

APPOINTMENTS.

HOUGHTON, E. R., *Assistant Surgeon.*—To rank as such from July 12, 1890.

BENEDICT, A. L., *Assistant Surgeon.*—To rank as such from July 24, 1890.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL ADDRESSES.

INTERNATIONAL UNIFORMITY IN ARMY MEDICAL STATISTICS.

An Address delivered before the Section of Military Hygiene, Tenth International Medical Congress, Berlin, August 7, 1890.

BY JOHN S. BILLINGS, M.D., LL.D.,
SURGEON UNITED STATES ARMY.

(Concluded from page 134.)

IT is impossible to publish the data for each individual form of the thousand and more varieties of disease which medical officers are called on to record, since to do so would occupy far more space than the amount of information thus obtained by the public would justify. We must, therefore, group the great majority of them according to some nosological system of classification; and herein lies one of our greatest difficulties. There is no uniformity in the system of classification in use in different armies, and there is no system which is satisfactory to one who is familiar with the recent advances in pathology. Even as regards the nomenclature of causes of death, the terminology of which is much more limited than that which must be used by the army medical officer in recording cases of disease, there is no uniform classification adopted in different countries. That it is very desirable to secure uniformity in nosological arrangement is admitted by every one; but is it possible to accomplish it? In attempting to answer this question we must fully recognize the difficulties which exist in each country in the way of changing its present methods.

In the first place, it is desirable that the classification for each army shall be such that its results can be compared with those given in previously published medical statistics of the same army, and also, with the published mortality statistics of its own country. Any changes, therefore, which render such comparison impossible are undesirable.

In the second place, it is admitted that no system of nosology at present in use is satisfactory, and, therefore, if an absolutely uniform system is to be prepared and adopted it will require a change in the form of statistics of every country, and these changes should affect the forms in which the mortality statistics of civil life are published, as well as those of armies and navies.

Taking all these facts into consideration, as well as the general characteristics of human nature which lead a man to think that his own plans, or the system of his own country is the best—which characteristics affect those having charge of the organization of army medical departments very much as they do other men—and also the fact that in view of recent discoveries it would be unwise at present to attempt to classify from the etiological point of view quite a number of forms of disease, it seems evident that it is not worth while now to attempt to secure a uniform and rigid system of nosological classification. When, however, we come to consider the forms of disease which are of the most frequent occurrence and which cause the greatest amount of disability and loss of life in armies, we find that it is not so difficult to suggest a system which will permit of comparison of the more important facts in the statistics of different armies.

If the data are given for each of the individual forms of disease above specified, we shall find that most of the more important difficulties have been practically overcome. For example, diarrhœas are included under one classification of diseases of the digestive organs, and in others in one of the sub-groups of the general diseases. In one classification phthisis pulmonalis is given under diseases of the respiratory organs, in another under the group of tubercular diseases, which in turn are classed with rheumatism. Tetanus is usually given under diseases of the nervous system, but if a new nosology were now to be constructed it would probably be placed with specific infectious diseases. Diabetes, or glycosuria, appears in one classification under diseases of the digestive system, in another under diseases of the urinary organs in another under diseases of the nervous system, and in still others under the heading of general diseases. But if the data for each of these forms of disease are given separately it is possible to make all the comparisons which are desirable between the statistics arranged in these widely different forms of classification. The chief difficulty, of course, occurs in the class of what are termed general diseases. If we can agree upon the groups into which these are to be divided, and as to what each group shall include, there is little difficulty in arranging a scheme for the classification of the local diseases. Among these general diseases the statistics of the following should be given separately from any system of classification whenever they occur among the troops, viz., cholera, yellow fever, plague, spotted typhus, relapsing fever, cerebro-spinal fever, diphtheria, tetanus, and specific influenza, or grippe. Excluding these from the grouping in addition to the specially important individual forms of diseases previously considered we should have groups of the so-called general diseases something like the following:

1. Acute contagious fevers, including more especially the ordinary eruptive fevers, such as measles, scarlet fever, and rötheln.

2. Septic diseases, due to pyogenic bacteria or their products.

3. Tubercular diseases, including all forms, with the exception of phthisis pulmonalis, which is to be given separately.

4. Diseases due to animal parasites, such as trichinæ, worms, etc.

5. Diseases derived from animals or so-called zoogenous diseases—glanders, anthrax, etc.

6. Tumors and new growths.
7. Debility and other unknown or vague causes.

The classification of the local diseases would then be the usual one, excluding as before the individual diseases of special statistical interest. It would include diseases of the nervous system, of the respiratory system, of the circulatory system, of the digestive system, of the genito-urinary system, of the absorbent system, of the locomotor system, of the eye, of the ear, of the nose and throat, and of the integumentary system.

Let us now see how far it would be possible to obtain data, in accordance with the individual items and groups of this classification, from the army medical statistics heretofore published. This is shown by the following table:

DISEASES AND GROUPS OF DISEASES GIVEN IN DIFFERENT ARMY MEDICAL REPORTS.

	Austrian army.	Bavarian army.	Belgian army.	British army.	French army.	German army.	Italian army.	Netherlands army.	U. S. army.
Smallpox									
Enteric or typhoid fever									
Acute contagious fevers									
Diarrhœa									
Dysentery									
Malarial fever									
Venereal diseases									
Primary syphilis	}	{	}						
Secondary syphilis	}	{	}						
Gonorrhœa									
Septic diseases									
Pulmonary phthisis									
Tubercular diseases									
Rheumatism									
Diabetes and glycosuria									
Scurvy									
Alcoholism									
Tumors and new-growths									
Malignant tumors									
Diseases due to animal parasites									
Diseases from animals (zoögenous)									
Debility and other unknown or vague causes									
Mental disorders									
Suicide									
Diseases of the nervous system									
Tonsillitis									
Bronchitis									
Pneumonia									
Diseases of the respiratory system									
of the circulatory system									
of the digestive system									
of the genito-urinary organs									
of the absorbent system									
of the locomotor system									
of the eye									
of the ear									
of the integumentary system									

The Belgian, British, Italian, Netherlands, and United States reports give only the number "admitted;" the Bavarian, French, and German reports give the number "admitted" and "total treated;" the Austrian report gives the "total treated" only.

Thus far, for the sake of simplicity, we have been speaking of the statistics of diseases only, not including injuries, and of those used in regular periodical reports in time of peace and not of those employed in setting forth the medical history of a campaign or war. As regards the general class of injuries and wounds of all kinds, the classification used in the regular periodical reports of the different armies is shown in the following table, the combinations with other data being substantially the same as those used in connection with the different diseases.

TABLE SHOWING INJURIES REPORTED FOR ARMIES IN REGULAR REPORTS IN TIMES OF PEACE.

	Austrian.	Bavarian.	Belgian.	British.	French.	German.	Italian.	Netherlands.	United States.
Burns									
Contusions									
Contusions and lacerations									
Contusions and sprains									
Dislocations									
Excoriations									
Fractures (not gunshot)									
Fractures (including all)									
Frostbite									
Heatstroke									
Incised, lacerated and contused, and punctured wounds									
Incised, punctured, and bit wounds									
Injuries									
Injuries, general									
Injuries, local									
Injuries, received in action									
Lacerations									
Luxations									
Shot wounds									
Sprains									
Wounds (not including injuries)									
Sore from riding or walking									
Other injuries									

The forms of statistics of wounds and injuries occurring in a campaign or war which have heretofore been given on the most extensive scale, are contained in the reports of the French Army in the Crimea, 1854–56, the British Army in the Crimea for the same period, War of the Rebellion, United States, 1861–65, and the statistics of the Franco-German war published by the medical department of the German army, for 1870–71. The data or combinations of data given in these reports with regard to wounds and injuries are indicated in the following table:

WOUNDS AND INJURIES.

	French in Crimea.	British in Crimea.	German army 1870–71.	U. S. army 1861–5.
Injuries of head				
of face				
of eyes				
of lower jaw				
of neck				
of back and spine				
of chest				
of abdomen				
of pelvis				
of sacro-lumbar region				
of iliac region and buttocks				
of inguinal region				
of perineum and genito-urinary organs				
of genital organs				
of ano-perineal region				
of shoulder				
of arm				
of elbow-joint				
of forearm				
of wrist-joint				
of hand and fingers				
of hip-joint				
of thigh				
of knee-joint				
of leg				
of ankle joint				
of foot and toes				

Data beyond *abdomen* not yet published.

Each group subdivided according to nature of weapon: 1, punctured and incised wounds; 2, shot wounds: 3, other injuries. And, again, according to parts injured, in: 1, flesh wounds 2, fractures.

Giving for each class also—complications, sequelæ, and operations.

The statistics with regard to disease given in the above mentioned reports of campaigns, vary greatly in fulness and form of combination. In the United States report of the war of 1861–65, the figures are given for the total admitted for each of 152 causes, for each month, for each color, for each of twenty-four localities or regions with the corresponding number of deaths and discharges.

In the report of the British Army in the Crimea the data are given for the total admitted for each of 101 causes, for each month, with the corresponding number of deaths. The total deaths are also given by age-periods, and for each arm of service by months, and the discharges are given by causes and arm of service.[1]

In the report of the German army in the campaign of 1870–71, the data are given for twenty-seven diseases or groups of diseases, for each month, for each arm of service, with the corresponding deaths.

In the report of the French army in the Crimea, the data are given by months for the total admitted and treated for each of seven forms of disease, with the corresponding number of deaths and transfers.

TABLE SHOWING SPECIAL DISEASES AND GROUPS OF DISEASES GIVEN IN MEDICAL REPORTS OF CAMPAIGNS.

	British in Crimea, 1854–57.	U. S. army, 1861–65.	German army, 1870–71.

Sore from walking or riding			
Other unknown or undefined diseases			

In statistics of disease and death an exceedingly important factor is age, and unless the data for certain individual causes are given by age-groups it is impossible to make such comparisons with the corresponding data relating to persons in civil life, or in other occupations, as are now required by scientific students of these subjects. We have no reason to hope that any substantial increase of our knowledge will come from mere gross sick-rates or death-rates, or from the proportion of deaths to cases for individual causes of disease. We have already a vast amount of statistics of this kind, which have been and will be useful, but it is improbable that more tables of this kind will open any new paths to knowledge. If, however, we can obtain data of this kind with age and race groupings, I think that they will indicate some new fields of investigation, and furnish valuable information.

[1] The report also gives for each arm of service the length of treatment of fatal cases for six selected causes and the deaths by rank.

TABLE SHOWING THE NUMBER OF SPECIAL DISEASES, WITH COMBINATIONS, GIVEN IN MEDICAL REPORTS OF CAMPAIGNS.

Number of causes				British in Crimea, 101	U. S. army, 1861–65, 152	German army, 1870–71, 27

Another factor in medical statistics the effects of which it is desirable to study in connection with certain forms of disease, is race. In armies which contain both white and colored troops, such as the British in India and the United States army, it is usual to give separate tables for each, and the only special precaution required is to give separately the data relating to white officers serving with such troops.

With regard to white troops, the regimental and corps organizations in most armies are such that the different races are to a great extent classed by regiments, as for example the Irish and Scotch, the Saxon and Hanoverian, the Hungarian and Bohemian, etc. In the United States army, men of all nationalities are mingled in each regiment, and being thus exposed to the same conditions as to locality, food, climate, nature of service, etc., the race data may become especially valuable when collected for considerable periods of time—say ten years—as indicating for certain races a tendency to, or comparative immunity from, certain forms of disease.

Statistics of previous occupations are of much more importance when applied to the results obtained in those countries where military service is compulsory for a certain period of time than in those where it is not. For the latter, as in England and the United States, the

only value of such statistics in times of peace is in connection with the data relating to recruits, and is sociological rather than medical. Where military service is compulsory, if not on all adult males, at least on a certain proportion of them, the data of previous occupation, although still chiefly valuable when taken in connection with the data relating to recruits, have some value in connection with the data relating to certain forms of disease such as phthisis pulmonalis, rheumatism and gout, malignant tumors, and diseases of the circulatory system and locomotor apparatus. Such statistics are given only in the reports of the Bavarian army so far as I have seen, and in these reports the data of age are not given, so that it is not possible to compare them with corresponding data obtained from civil life.

For scientific purposes it appears to me desirable that the tables should deal chiefly with the total disposed of and not with the total number treated. For administrative purposes it is, as I have said, desirable to know the total loss of effective strength, which can only be done by taking into account those remaining under treatment at the end of the period for which the report is made, and in the study of causes of disease in relation to season, locality, etc., the number of admissions for each cause is the most useful factor, but the data to be used for advancing our knowledge of the effects of certain forms of sickness in their relation to locality, season, age, race, etc., should be derived solely from the completed cases. For such completed cases, then, I would suggest that the following combinations of data be given in the tables, viz.:

Table A., showing for the total number disposed of by certain causes and groups of causes, the number returned to duty, the number died, the number discharged, the number invalided otherwise disposed of, and the average duration of treatment, with ratios per thousand of mean strength for the total disposed of, and the ratio per thousand of all disposed of, for the deaths, discharges, and invalided. This table should be made out for the whole army for each year; it should also be made out for such subdivisions of locality as may seem desirable in each country for the total period under consideration; for the total troops in each arm of service, and for each of not less than five groups of ages. For each individual disease, and for each group of diseases adopted a table should be given, showing, with distinctions of five groups of ages and of under and over one year of service, the total number of cases disposed of and the number of deaths for each.

TABLE A.

Diseases and groups of diseases.	Disposed of.												Average duration of treatment.	Total disposed of per 1000 mean strength.
	Total disposed of		Returned to duty		Died.		Discharged.		Invalided.		Otherwise disposed of.

Etc.													
Etc.													
Totals													

We now come to the question of the mode of obtaining the data for such statistical reports as must be prepared at the central office of the medical department of an army, whether these are intended only for the information of the central office and for that of the War Department, or for publication. There are two essentially different ways of obtaining this information. The first is to throw a large part of the work of statistical compilation upon the medical officers of the several posts or commands, requiring them to transmit periodical forms monthly, quarterly, or annually, on which forms are given the medical statistics of their commands for the period in question in greater or less detail.

The other is to require the medical officers to furnish the complete data with regard to each case to the central office, where the work of compilation is chiefly done, leaving to the medical officer of the post or command the duty of preparing such statistics only as are required for the information of his commanding officer or of the commanding officer of the department. The conclusion which has been arrived at in the Surgeon-General's Office at Washington is, that the second method is preferable, and our present forms are, therefore, prepared upon this basis. They are large sheets on which are given the name, rank, company, regiment, age, race, birthplace, length of service, cause of admission, date of admission, complications and sequelæ, result and date of disposal (specimen submitted) of each person taken on sick report during the period for which each report is made, and the name and identification data for each name remaining on sick report at the beginning of the period, without attempting to sum these up in all the various combinations of which the data are susceptible—merely the gross morbidity and gross death-rate being stated. When these sheets are received at the central office, the individual data are copied off on cards which are then assorted in all the different combinations which are desired. I see no good reason why all this information should not be furnished by the medical officers of posts and commands upon cards—one for each individual case, when completed by return to duty, transfer, death, discharge, etc. At the end of the year cards should be forwarded for all cases then under treatment, and subsequent cards should be forwarded for these cases when completed. Cards of different colors, or printed with different colored inks, might be used for classification in various ways. The use of individual cards or slips is now recognized by all experienced in such work as the most convenient means of securing all the various combinations desired in vital and medical statistics, with the least amount of skilled labor. If desired, much of the sorting of the cards can be effected by mechanical devices, or they can be punched, and any combinations counted by means of the Hollerith electrical apparatus for that purpose. When not required for statistical uses, these cards can be filed in the alphabetical order of the names of the men to whom they relate, and in this way the medical and surgical history of each case in which there have been successive admissions on sick report will be brought together.

From much practical experience with this card system of records, I can confidently recommend it as the best method of securing and compiling medical and surgical statistics, and of preserving in convenient form the original data upon which such statistics must be based, and from which new combinations may hereafter be desirable. Herewith are presented the form of card used in the statistical division of the Surgeon-General's Office at Washington, and also the form upon which cases of injury or surgical operation are reported, together with forms of cards used in the Vital Statistics Division of the United States Census.

The great objection to relying exclusively on forms of reports compiled by individual medical officers, on which the detailed data for each individual are not given, is that they do not permit of numerous combinations which the statistician may desire to make when he has large numbers at his command, but which it is not worth while to provide space for in a form which is to be used for a single post or regiment.

For example, the form of monthly report of sick and wounded for administrative purposes proposed by Surgeon J. R. Smith, U. S. A., and approved by the Washington International Congress,[1] gives the data for individuals only for those dead or discharged, and it is, therefore, impossible to obtain from it with regard to those who do not die or are not discharged—*i. e.*, the great majority of cases—the data relating to age, race, duration of treatment, rank, etc., in their various combinations, with different forms of disease at different seasons of the year, which it may be desirable to compile for scientific purposes. It appears to me best to use forms of this kind for administrative purposes, and in addition to use the card system, combined with detailed reports of the more important cases, as the chief reliance for the collection of data to be compiled for scientific purposes.

We now come to the last subdivision of the problem under consideration, namely: Will it probably be possible to induce the different governments to agree to a uniform system of publication of the data and combinations of data which are required to increase our knowledge of the causes and results of disease and injuries? It appears to me that the answer should be "Yes." It is not likely that uniformity can be secured in the forms of returns of sickness and injury which are chiefly valuable for administrative purposes, since these must depend largely upon the organization and mode of administration of the individual armies, upon the duties of the chief medical officers of corps or departments, upon the amount of centralization in administration, etc., and it is not worth while to lose the substance by grasping too insistently at the shadow. But if the central office can obtain, by some such simple method as the card system above referred to, the statistical data for each completed case, and can at the same time obtain the data with regard to the whole body of men among whom the sickness and injuries have occurred—the mean strength data, in other words—for the purpose of computing ratios, it can then make careful studies of individual forms of disease or injury for long periods in all their various relations, and this without in any way interfering with administrative statistics, or being fettered by rigid forms adopted without sufficient prevision of the points which future discoveries may show to have been of scientific importance.

[1] See Transactions Ninth International Medical Congress Washington, D. C., 1887, vol. i. p. 71, and vol. v. p. 29.

To sum up then, Army medical statistics of scientific value relate mainly to individual forms of disease and not to nosological groups, and are to be derived from individual records of completed cases; they should cover longer periods than one year to give valuable results in medical geography, and should be given with more details as to age, race, length of service, and average duration of cases than have heretofore been supplied in published statistics of this kind. Absolute uniformity is not to be expected nor is it desirable, but such statistics of different armies can be made comparable with each other and with the morbidity and mortality statistics of civil life to a much greater extent than has been done heretofore. The object of this paper is to establish a few general principles upon which we can agree and in accordance with which we may work in the future, rather than prescribe precise forms or to criticise the details of those heretofore employed.

ORIGINAL ARTICLES.

SOME NEW BACTERIAL POISONS; THEIR CAUSAL RELATION TO DISEASE AND THE CHANGES IN OUR THEORIES SUGGESTED BY THEIR ACTION.

By VICTOR C. VAUGHAN, M.D.,
of Ann Arbor, Michigan.

In a paper[1] read in May, 1888, before the pædiatric section of the New York Academy of Medicine, I stated, as my belief, that the ordinary summer diarrhœa of infancy is not due to specific pathogenic microörganisms, but that it is due to putrefactive or saprophytic germs, which induce disease and death by the elaboration of chemical poisons in the intestines.

Able and skilful bacteriologists, among whom Booker in this country and Escherich in Germany deserve special mention, have made diligent search for the specific bacterium of summer diarrhœa, but no such organism has been found, and the probabilities are that it does not exist. The failure to find a specific germ has not arisen from the absence of bacterial species. On the contrary, the number of varieties and species has been confusingly great; but there is no constancy in the presence of any of them. In his first communication Booker reported the isolation of eighteen species, and he has subsequently added fifteen new ones to the list. Forms which appeared frequently one summer were wholly wanting the next. The large number and the great variety were not due to contamination, for the work was done with unusual care, the cultures being taken directly from the intestines of the sick child. Thus, it will be seen that in the case of this diarrhœa, which is so frequent during the hot eason, and which has been diligently studied by a number of the best bacteriologists, the very first of Koch's rules has not been substantiated. In view of these facts the following question quite naturally suggests itself: "Are there not two or more germs which are capable of inducing this disease?" With the hope of answering this question I asked Dr. Booker to send me some of his cultures. This he did last February, and with three of these species I did the following work. The germs used are the *X*, *a*, and *A*, of Booker.

Flasks of sterilized beef-broth were inoculated separately with these germs and kept in the incubator at 37° C. for ten days. At the expiration of this time the contents of the flasks were filtered twice through heavy Swedish filter-paper, and during the second filtration the filtrate was allowed to drop into a large volume of absolute alcohol, which had been feebly acidified with acetic acid. A voluminous flocculent precipitate resulted in the filtrate from each of the cultures. After subsidence of the precipitate the supernatant fluid was decanted and the precipitates from the cultures of *X* and *a* were dissolved in water and reprecipitated with absolute alcohol. The precipitate from *A* proved to be so sparingly soluble in water that, after thorough agitation with water, it was caused to subside by the addition of a large volume of absolute alcohol.

The precipitates were then collected and speedily transferred to a vacuum and allowed to dry over either sulphuric acid or caustic potash. They are proteid in character, yet differ in character from ordinary proteids and from one another. That from *a* forms on the porous plate a scaly, dark substance, which is easily soluble in water. From its aqueous solution it is not precipitated by heat or nitric acid, alone or combined. It is not precipitated by saturation with sodium sulphate or by a current of carbonic acid gas, and, therefore, cannot be a globulin. It is precipitated by saturation with ammonium sulphate, and, consequently, we cannot call it a peptone. It gives the xantho-proteid and biuret reactions, and on the application of heat gives off the odor of burning feathers. The proteid from *X* is lighter in color and less readily soluble than that from *a*, but in the other reactions the two agree. That from *A* is practically insoluble in water. The chemical properties of these substances will receive further attention.

All are highly poisonous. Small quantities injected under the skin of kittens and dogs cause retching, vomiting, purging, collapse, and death. Ten milligrammes of thedried proteid from *a* killed a large guinea-pig within twelve hours. A much smaller amount proved equally fatal, but the time required was much longer. When very small, but unweighed, quantities were used, many days (from ten to thirty) passed before death followed. A small percentage of the animals experimented upon with

[1] The Medical News, June 9, 1888.

the very small doses have remained permanently unaffected.

The post-mortem appearances in all the cases have been practically the same. The small intestines are pale throughout and tightly constricted in places. The heart is in diastole. Marked changes in other organs have not been observed.

These experiments show that three germs, which differ morphologically from one another sufficiently to be classified as different species, form poisons which also differ in their chemical properties, but which produce the same symptoms and post-mortem appearances. It must be remembered that no one of these germs is constantly present in summer diarrhœa. Sometimes *X* is found almost in pure culture, while in other cases this is absent and *a* or *A* abounds, and in a still greater number of cases no one of these three can be found and we have in their stead another or others of Booker's long list. These three were taken at random from the number which Dr. Booker has isolated, and it is probable that many more are equally powerful.

While *X*, *a*, and *A* differ morphologically, physiologically they are near akin. All are capable of producing powerful poisons. I propose that such germs be called *toxicogenic*. Not only do *X*, *a*, and *A* resemble one another in producing poison, but their poisons cause similar effects.

Germs, in their causal relation to disease, cannot be classified simply from their morphology; we must also understand their physiology; we must know something of the chemical changes which they cause by their growth.

Bacteria are divided into the parasitic and the saprophytic. The obligate parasite can live only on living matter; the obligate saprophyte can feed only on dead matter. The bacilli of leprosy and of syphilis are probably obligate parasites. They have not been grown on artificial media. True parasitic germs do not prove speedily fatal to their hosts. Their own continued existence depends upon the continued existence of their host, or on their transference to another host. Bacteriologists have taught that the true parasitic germs are the most deadly. This cannot be true. On the other hand, it is for the well-being of the saprophytic germ to destroy life, for in so doing such a germ furnishes itself with more nutriment and improves the conditions of its own existence. But, it will be asked, How can a saprophytic germ live in the human body and how can it prove fatal? The bacterium growing in the intestines of man does not necessarily feed upon living matter. The food before absorption is not endowed with vitality. Saprophytic germs will grow in the peptone preparations in the test-tube; why should they not feed upon peptones in the small intestines? The excretions passed into the intestines are not living, and upon these also, saprophytic germs may feed. Growing in the intestines saprophytic germs induce disease and death by producing chemical poisons which are absorbed.

These facts, if they be true (and their truth seems to me to be demonstrated by the facts shown above, that three different saprophytic germs produce poisons capable of causing the symptoms of summer diarrhœa, and death), materially alter the teachings of the bacteriologist. The tendency of such teachings has been for the past few years toward the belief that filth in and of itself cannot cause disease. That filth must be infected with some parasitic or specific germ in order to cause disease, is a doctrine which has met with acceptance. If my deductions from the above experiments be true, there is no specific germ in summer diarrhœa. All toxicogenic germs are dangerous when introduced into the intestines. They will there find an abundance of dead matter to feed upon. Not only is this true, but they will find that kind of dead matter which is best suited for their growth. It is generally conceded that saprophytic germs can only feed upon, or at least thrive best only in the presence of, diffusible proteid material. For this reason peptone is an important constituent of the nutritive gelatin which we use in our culture-tubes. In the intestines these diffusible proteids abound. Many of the saprophytic toxicogenic germs are anaërobic, and in this respect also, the conditions prevailing in the intestines favor their growth.

Again, if these deductions be correct, we have, in the question of the prevention of the intestinal diseases of childhood, quite a different problem from that presented by those who believe in a specific germ. We have to guard against the introduction into the child's stomach not of a single germ which abounds in certain localities, but we must protect the child from a whole host of toxicogenic germs which are widely and abundantly distributed. Milk infected with any one of a dozen different organisms may cause disease and death.

But, says one, if this be true, if there are so many possible causes of these diseases, how is it that so many children manage to live? The mortality must be admitted to be great, when we remember that more than one-fourth of the children born in the United States die before they reach five years of age. However, nature has not placed about infancy so many dangers without making some provisions to protect the child. In the first place, as has been shown by numerous experiments, the infant taking its food directly from the clean breast of the healthy mother gets its food wholly free from germs of all kinds. Moreover, both in infancy and in adult life at least one of the digestive secretions,

the gastric juice, is a powerful germicide, especially destructive to those organisms which infect by the way of the intestines. So far as experiments have been made, there is no germ which is known to have a causal relation to an intestinal infectious disease and which is not destroyed by the action of a healthy gastric juice, when exposed to such action for only a few minutes, or for half an hour at most. As Escherich has shown, one of the great dangers in artificial feeding lies in the greater power of cow's milk to neutralize the acid of the gastric juice. Overfeeding is also an important factor in the production of the intestinal diseases of infancy. I believe with Bunge[1] that the chief office of the acid of the gastric juice is to protect us against infection through the intestines. Certainly every step in the process of digestion could be carried on without the presence of acid in the stomach. Even the digestion of proteids proceeds much more rapidly in the alkaline secretion of the pancreas than in the acid one of the stomach.

Again, we are probably to a large extent protected from the injurious effects of these poisons formed by the saprophytic germs in the intestines by the absorbing mechanism of the intestinal walls. We know that in health we are thus protected from the injurious effects of certain products of normal digestion. The proteids of our foods are converted into peptones, but there are no peptones in the blood, even in the portal blood. If peptones are injected into the blood they are poisonous. In health they are changed into serum-albumin and globulin while they are being absorbed. Now, these new bacterial poisons are proteid in character, as has been shown, and when formed in the intestines the only way in which we can be saved from their deleterious effects is by the action of the absorbing mechanism of the intestines upon them, converting them into harmless proteids. Right here lies the explanation of the greater susceptibility of the infant to these poisons formed by the saprophytic germs in the intestines. The rapid absorption from the intestines of the infant renders the passage of these poisons into the blood unchanged more easy and certain. In this is also to be found the explanation of the favoring influence of constitutional disease, and of prostration from heat, on the frequency and fatality of summer diarrhœa. Anything which lowers the general vitality of the child diminishes the normal resistance of the living cells to the proteid poison.

To conclude this part of the discussion, we may say that any germ which is capable of producing a poison in a flask containing a proteid material is not a safe one to introduce into the intestines. It is not necessary, in order to show the dangerous character of a germ, to prove its pathogenic property by inoculating an animal through the blood. In the blood the bacterium meets with very different conditions from those existing in the intestines.

The same general statements which I have made concerning the summer diarrhœa of infancy will, I believe, hold good in the case of enteric fever. I have recently reported the isolation of proteid poisons from cultures of two germs found in drinking-water supposed to have caused typhoid fever.[1] But, says one, the specific germ of typhoid fever has been found, and is the well-known Eberth bacillus. It is true that this organism is found in the spleen practically in every case of death from typhoid fever, and this is the sole evidence that we have of its relation to the disease. Continued fever with ulceration of the small intestines can be induced in the lower animals by a number of saprophytic germs. The great diversity in the symptoms and course of the continued fever in different sections of the country, and in the same locality at different times, seems to me quite an argument against the specific character of the disease. There is now fair promise of a satisfactory explanation of the true relations between the Eberth bacillus and typhoid fever. The bacterium coli commune is an organism which is constantly present in the healthy large intestine. In certain diseased conditions it finds its way into the internal organs. Typhoid fever is one of these diseases, and Rodet and Roux[2] conclude from their studies that Eberth's bacillus is only a degenerative form of the bacterium coli commune. Just what *rôle* this germ, by altering its place of residence, plays in the causation of the disease we do not know. But practically this observation is of great importance, because, if it be true, filth, in and of itself, may cause typhoid fever.

The fact that these new bacterial poisons may cause death, when injected under the skin in small amounts, after from ten to thirty days, is of great interest. We cannot believe that chemical poisons increase in amount in the body. They probably have a catalytic action, setting up a series of changes from which death results. The great majority of catalytic changes consist in the splitting up of complex molecules into simpler ones. Such a conversion is accompanied by the liberation of heat. In this we may have an explanation of the causation of fever in the infectious diseases. Some of the proteid of bacillus *a* was injected under the skin on the backs of two dogs. Retching, vomiting, and purging began within half an hour and continued for two days, after which the dogs slowly recovered. During these two days the dogs were much exhausted, and lay for the greater part of the time with their heads on

[1] Physiologische Chemie.

[1] The Medical News, June 14, 1890.

[2] Comptes Rendus, February 21, 1890.

the floor, and shivering; but the rectal temperature during this time varied from 102.5° to 103.5°.

The following experiment was made with great care, but must be repeated before any positive conclusions can be drawn:

Two guinea-pigs were treated with hypodermic injections of one of these poisons. Within twelve hours both were dead. Plate-cultures made from the liver, spleen, blood, brain, and spinal cord remained sterile. Small quantities of the brain and spinal cord were rubbed up in a sterilized Petri dish with sterilized water, and a Pravaz syringeful of this emulsion was injected under the skin of each of four guinea-pigs. These animals seemed to be very excitable the next day, throwing themselves about violently in the cages when slight noises were made about them. Three out of the four have died, the first after sixteen, the second after eighteen, and the third after twenty days. This would indicate to me that the poison accumulates in the brain and spinal cord. However, similar experiments must be made with the blood and with emulsions similarly prepared from other organs of the body.

The following question has arisen in my mind: If these small cellular organisms, the bacteria, are capable of converting the ordinary proteids into such powerful poisons, why is it not reasonable to suppose that the glandular cells of our own bodies may under abnormal nervous stimulation or excitement also convert the ordinary proteids into similar poisons? Is the story of the nursing mother's milk becoming poisonous to the infant after great fright altogether unreasonable and wholly unexplainable? May not the hunted dog, when pursued and stoned, become rabid on account of the improper action of the cells of the salivary glands? These and other questions of a similar character quite naturally present themselves, and I have no doubt that in time a satisfactory answer will be found for them.

The discovery of these new bacterial poisons promises materially to alter our views of the nature of disease in many important respects.

Some four years ago Mitchell and Reichert[1] announced the discovery of poisonous proteids, a globulin and a peptone, in the venom of serpents. At that time their work was criticised, notably in Germany, on the ground that poisonous proteids were not believed to exist, but there can no longer be any such doubt. In 1888 Christmas[2] obtained from cultures of the staphylococcus aureus a proteid which, when injected into the anterior chamber of the eye or under the skin, caused suppuration. Haskins[3] has isolated from cultures of the bacillus anthracis a poisonous albumose. Very recently Brieger and Fränkel[1] have obtained from cultures of Löffler's bacillus of diphtheria a poisonous albumin which induces the paralysis and other symptoms of the disease, and which, when used in small quantity, produces death, sometimes after a period of twenty or thirty days. The same investigators have shown that similar bodies are produced by the germs of cholera and tetanus, and by Eberth's germ. Baginsky and Stadthagen[2] have found a poisonous proteid in growths of the summer diarrhœa bacterium, discovered by the former. These numerous investigations leave no room for doubt as to the existence and importance of these bodies. I have no doubt that they will prove to be the active agents in some cases of milk- and cheese-poisoning. Indeed, in the article which I read two years ago, referred to in the beginning of this paper, I predicted the discovery of new chemical poisons which would prove to be the active agents in the causation of the catarrhal diarrhœas of infancy. The new poisons which I have isolated from growths of the germs of Booker make good this prediction.

This paper would be incomplete if we did not look at another side of the question. While the harmful proteids play such an important part in the causation of disease, there are other proteids which serve to protect us against disease. The germicidal properties of the blood have recently attracted much attention. These properties have been shown to reside, not in the white corpuscles or other formed elements, but to be due to the presence and activity of certain proteids. This has been satisfactorily demonstrated by Büchner, Sittmann, and Orthenberger;[3] also by Fodor.[4]

Thus, it will be seen that the study of the proteids of the body and of those altered by bacterial growths promises to throw much light upon the causation, prevention, treatment, and nature of disease.

We may formulate the conclusions which are apparently justified by the present state of our knowledge, in the following propositions:

1. Man is attacked by the infectious diseases either through the alimentary canal or through the blood (or lymph).

2. The gastric juice is a physiological guard against infection by the way of the intestines.

3. Additional guards against infection by the intestines are probably to be found in the absorbing cells of the stomach and intestines.

4. Susceptibility to the intestinal infectious diseases is increased when for any cause these physiological guards are defective.

[3] Archiv für Hygiene, B. 10, H. ii., 1890.
[4] Centralblatt f. Bacteriologie u. Parasitenkunde, B. 8, No. 24, 1890.

5. All toxicogenic germs are dangerous when introduced into the intestines, and their capability of doing injury lies in their production of chemical poisons.

6. Many of these poisons are proteid in character.

7. These poisonous proteids most probably act by catalysis.

8. In the splitting up of complex molecules into simpler ones heat is liberated and fever manifests itself.

9. The physiological guard against infection through the blood or lymph lies in the germicidal action of the proteids of these fluids.

10. Susceptibility to infection through the blood or lymph is increased by impoverishment of these fluids.

11. We can continue to treat consumption and other systemic diseases by the employment of liberal diet, exercise in the open air, and constitutional remedies without being unscientific in our practice.

12. Filth, without being the bearer of a specific germ, is a cause of disease.

13. Wherever man pollutes the soil about him, the air which he breathes, and the water which he drinks, with his own excretions, there enteric fever will be found.

14. In their causal relation to disease, germs cannot be classified without a knowledge of the chemical changes which they induce.

15. While certain bacterial poisons can result only from the growth of certain germs, other poisons similar to one another in their action, though probably not identical, may result from any one of a number of organisms. In the former case we have such diseases as anthrax and smallpox, with their practically constant symptoms and well-marked course: in the latter case we have such diseases as the summer diarrhœa of infancy and enteric fever, with their varying symptoms.

PERMANENTLY GOOD RESULTS OF EXCISION OF THE MEMBRANA TYMPANI AND MALLEUS IN A CASE OF CHRONIC AURAL VERTIGO; ALSO IN A CASE OF CHRONIC SUPPURATION OF THE TYMPANIC ATTIC.[1]

BY CHARLES H. BURNETT, M.D.,
AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

As two years and more have elapsed since the first of the two cases I narrate was operated upon and a year in the second case, I have considered the results as worthy the attention of this Society; because, no matter how good the immediate result of any operation may be, a just estimation of the operation and its results can be formed only after the lapse of considerable time.

The case of chronic aural vertigo was operated upon in May, 1888, and a report of the case and the operation was read at the meeting of this Society, in July, 1888. Briefly recapitulated, the case was as follows:

Miss D., aged thirty-one, was first seen by me in November, 1881, the case being diagnosed as one of chronic catarrh of the left middle ear, attended with annoying tinnitus and with hearing of only six inches for isolated words. All known methods of treatment for such cases failed to relieve the deafness and tinnitus.

There was no aural vertigo at that time. I lost sight of the case for six years, when I received a letter from the patient stating that she was suffering greatly from tinnitus in the left ear and frequent attacks of severe vertigo, which at times obliged her to cling to a lamp-post or a similar object when she was attacked by vertigo in the street. Upon inspection of the ear in May, 1888, it was found that the malleus was adherent to the promontory, and the constant retraction of the chain of ossicles thus produced was deemed the cause of the tinnitus and vertigo.

The patient was etherized and the membrana tympani and malleus excised. The tinnitus and vertigo immediately ceased and have never returned. A new membrana tympani formed in this case in the course of two months and has persisted to the present time. The hearing has remained unchanged.

A letter from the patient a few weeks ago informs me that her health and strength, previously impaired, are now excellent, that the ear remains free from subjective noise, and that the vertigo has never returned. More than two years have elapsed since the operation which gave the relief. As far as I can discover, this is the first case of chronic aural vertigo (so-called Ménière's symptoms) reported as cured by an operation such as I have described. The case furthermore proves the mechanical origin, and not a neuropathic one, of many cases of so-called Ménière's disease, a point I have long contended for.

The second case was a typical one of that inveterate class, known as "attic disease," in which a chronic suppuration in the tympanic attic has its only outlet through the membrana flaccida, and in my experience always bids defiance to all modes of treatment heretofore proposed for its cure.

This case came under my observation two years ago, and gave the following outline of history:

The patient, a lady of twenty-three, stated that she had had some catarrhal symptoms in her nose, throat, and ears in childhood, and that the tonsils were deemed worthy of excision, and this was followed by earache and dulness of hearing in both ears. These symptoms soon wore off and were

[1] Read at the annual meeting of the American Otological Society, Hotel Kaaterskill, July 15, 1890.

forgotten, excepting that the right ear, the one now suppurating, never heard well after the excision of the tonsils.

In 1882, six years before first consulting me, suddenly, and without previous warning of any kind, the right ear felt *stopped*. She says that examination by her physician at that time revealed a polypus in the right ear. The polyp was removed, and since then there has been a slight, nearly constant, offensive discharge from this ear, but hardly enough to flow from the meatus. In the meantime numerous polypi have been removed from this ear, probably from the region of the perforation in the membrana flaccida, by surgeons in this country and in Europe, but no permanent relief has followed these operations. This want of success was due to the fact that the treatment had been one of symptoms and not of the disease itself, which in reality was a necrosis of the head of the malleus, as shown by the operation I performed.

At the time I first examined the case the hearing in the affected ear was *nothing*. The membrana vibrans was found intact and dry, retracted, white, and shining; in the membrana flaccida there was a large perforation, through which the white neck of the malleus could be seen, and from which a scanty, sticky, offensive discharge came, clinging mostly to the upper wall of the external auditory canal. I, too, then proceeded to treat symptoms, as my predecessors in the case had done, and for one year I applied all known rational means of treatment to the case, by antiseptic injections into the attic cavity with the tympanic syringe, and by snaring off small polypi from time to time as they appeared around the perforation; but all without any good result, simply because I had not reached and could not get at the true disease in the attic, so long as the membrana tympani and the malleus barred the way.

Therefore, on July 29, 1889, the patient was etherized, and under illumination of the auditory canal by means of the electric head-lamp, as devised for Dr. Sexton by the River and Rail Electric Light Company of New York, the membrana tympani and the malleus were excised. The head of the malleus was found half destroyed by necrosis in its free anterior portion, its articular surface with the incus being normal. The other ossicles were not seen, but as far as could be decided by the probe, there were no necrotic spots anywhere else within the tympanic cavity—an opinion which was strengthened by the speedy healing of the diseased region after the operation.

Here, then, was the cause of the previously incurable purulent discharge from the attic space. The ligaments about the neck of the malleus were very tough and broad, and had acted as a diaphragm between the attic and the atrium, and also as the floor of a sinus running from the diseased malleus to the perforation in the membrana flaccida.

The steps of the operation of excision consisted in:

1. An incision behind the short process, with a slender blade.

2. Through this initial incision a round-pointed blade, curved in the plane of its broad surface, was introduced, and being kept close to the manubrium, below the insertion of the tendon of the tensor tympani, was pressed upward against the latter, and the tendon thus severed.

3. Then a straight blade, with rounded blunt end, was used to cut around the membrana tympani in the annulus tympanicus, thus entirely detaching it, and severing the hammer ligaments at the neck of the bone.

4. Instead of forceps the polypus snare was now used to seize the malleus, being passed around the manubrium, and the malleus with the membrana tympani was removed from the ear.

The slight hæmorrhage was controlled by mopping the fundus of the ear with a 4-per-cent. solution of cocaine muriate. During the operation the fundus of the ear was mopped frequently with a 2½-per-cent. solution of carbolic acid. After the operation the meatus of the canal was lightly tamponed with cotton sprinkled with iodoform, and left in place for twenty-four hours.

The next day the patient went about the house. The cotton tampon was slightly discolored on its inner end with a pinkish serum. There was no purulent discharge and there has not been any since the operation, nearly twelve months ago.

The iodoform tampon in the auditory canal was discontinued in four or five days, and one containing powdered boric acid sprinkled over it was substituted and worn for a week longer. Then simply a little cotton pellet was worn in the meatus, in the open air, to protect the exposed tympanic cavity. On some days the tampon was a little moistened with a serous fluid, but this soon ceased to appear. The absence of any reaction and the tendency to rapid healing in this case I am disposed to attribute largely to the antiseptic measures during and after the operation.

By August 12th there was no discharge of any kind from the ear. The hearing was found to be a little improved; about a foot for loud words.

Aug. 19. Still no discharge. The mucous membrane of the promontory is pale and rough, but entirely dry. The region of the membrana flaccida is narrowing. Hearing equals a whisper at six inches.

The patient now went on a tour to the Adirondacks, *free, for the first time in seven years, from the annoyance of a running from the ear and the care it demanded.*

The patient was not seen again until September 25th, when it was found that a new membrane had formed from the segment of Rivinus, the region of the membrana flaccida, down to the promontory. There was no discharge. The hearing for whispered words, was two to three feet.

October 11. The delicate membrane, bluish and transparent, rises and falls under gentle suction with the pneumatic speculum. The hearing is *nine feet* for isolated words in ordinary conversational tone.

At the present time the hearing is fifteen feet for whispered words.

Here, therefore, is offered an account of a case of chronic purulency and deafness, caused by necrosis of the head of the malleus and altered tension and conductivity in the ossicles, cured of the discharge and the deafness by excision of the useless membrane and a necrotic malleus. The cure of the purulency is easily explained, but the improved hearing is not as easily explicable. I venture to suggest that the conducting power of the ossicles was interfered with by the presence of pus about the ossicles in the attic, and by the pathological bands about the malleus already mentioned, which prevented ready vibration. Also the diseased condition of the head of the malleus loosened its articulation with the incus, and impaired its leverage on the latter. Hence, a wave of sound falling on the membrana and malleus could not transmit its inward oscillations to the incus and thence to the stapes and the labyrinth.

When the membrana tympani and the necrotic malleus-head were removed from the attic, waves of sound fell directly upon the incus and the stapes and were conveyed to the labyrinth. As the new membrane formed and rested against the ossicles remaining, its expansion offered a broader surface to the waves of sound, and possibly helped to increase their leverage on the remaining ossicles, thus transmitting more sound and increasing the hearing. The continuance of this normal stimulus to the movements of the stapes in the oval window gradually overcame the partial ankylosis which had ensued at that point, from disuse, and the hearing, in consequence, has *steadily improved* since the operation from nothing to *fifteen feet* for whispered words.

Let us suppose that the chronic purulency of the attic had been, or could have been, cured by injections through the perforation in the membrana flaccida into the attic cavity. The hearing would not have been improved, because the impaired malleus-head and the pathological bands around the neck of the malleus would not have been removed, and hence the impaired mobility of the incus and stapes would still have remained as a hindrance to hearing.

We see, therefore, that the operation of excision of the membrana tympani and the malleus offers not only a great means of curing chronic purulency, especially of the attic, but also of relieving deafness due to a stiffened membrana and ossicles, by the removal of pathological bands prohibiting free oscillations in the ossicles, and by thus permitting sound-waves to fall directly upon the stapes in the oval window.

Longevity in Norway.—A recently published government report from Norway shows an increased average longevity for that country. The average duration of life there for males is 48.3 years, and for females 51.3 years.

FISTULOUS ESCAPE OF LIGATURES AFTER PELVIC OPERATIONS.[1]

By MARIE B. WERNER, M.D.,
of Philadelphia.

As the science of abdominal surgery advances, we feel that it is not a report of successful operations alone, but the number of absolute cures, which establishes a reputation and makes the successful surgeon. Since the days when Lister first laid down the rule for antisepsis, which in turn gave birth to the crowning aid to surgery, thorough asepsis, the rate of mortality has diminished remarkably. The number of abdominal sections for various lesions increased, and with the number of recoveries the dread of such surgery diminished. Those earnestly engaged in effecting lasting cures soon began to see that it was not always recovery from an operation which meant a cure. The patient was not yet always safely landed; fistulæ, secondary adhesions, painful stumps, or unfinished operations, marked the shoals upon which the hopes for a perfect cure might be wrecked. It becomes our duty to study, like the successful navigator, these shoals in detail, and, if possible, to place the danger signal conspicuously in our minds, in order to be able to avoid a second exposure to similar dangers.

The reports of the most successful operations prove that rapid aseptic work, with as few instruments and sponges as possible, a clean stump, light ligatures applied closely to the uterus and with the ends cut short, and thorough irrigation prevent many of the complications. If there is much oozing from torn adhesions, or if pus is present, the drainage-tube becomes a valuable aid, provided it is properly cared for, cleaned at intervals of twenty or thirty minutes with a syringe, and removed as soon as the effusion becomes serous and less than a drachm at each removal.

Last but not least, comes the importance of including muscle and fascia in closing the abdomen. The fact that various gynecological societies have taken up the discussion of the behavior of ligatures after the removal of diseased uterine appendages induces me to record the following cases. The first was my own operation; the second case placed herself under my care three months after operation.

Knowing full well that there must always be a cause for unexpected happenings, I was anxious to satisfy myself of the cause in these cases, and I think that I succeeded.

Case I.—Operation in March, 1887. Right ovarian cyst; cyst-walls friable, and adhesions present. The ligature was of Chinese twisted silk and of

[1] Read before the American Medical Association, May, 1890.

Operator.	Operation.	Ligature.	Drainage.	Remarks.	History of Fistulæ.
Dr. W. H. Parrish, 2 cases, personal communication.	Double ovariotomy.	Black silk figure-of-8, one side, shoemaker's knot on the other.	No.	Both ovaries cancerous, one presenting a large tumor of about twenty pounds, the other the size of a large orange. General condition poor.	Fistula; two months later shoemaker's ligature discharged and fistula closed spontaneously.
	Removal of appendages on both sides.	"Rather large Chinese ligature," figure-of-8.	Yes.	Syphilitic negress; confirmed drunkard, unruly, and walked across the ward on second day, the glass tube *in situ*. Fistulous opening in lower angle of wound.	Nine months after operation removed one ligature with hooked end of small probe. Subsequently a counter opening was made, per vaginam, by another gentleman no avail. Later, laparotomy by a third resulted in death.
Dr. Charles M. Wilson, personal communication.	Ruptured ectopic gestation of six months.	Staffordshire knot.	.....	.....	Six months later one of the ligatures ulcerated its way out through the abdominal cicatrix.
Dr. H. M. Weeks, personal communication.	Ectopic gestation, November, 1888.	Twisted silk No. 3, figure-of-8.	Prolonged drainage; tube cleaned by irrigation and the long syringe with distilled water.	....	Ligature came away five months after the operation.
Dr. H. T. Hanks, reported to the N. Y. Obstet. Soc., Jan. 7, 1890.	Ruptured ectopic gestation.	.....	Yes; irrigation twice daily.	"The right broad ligament through which the hæmatocele had ruptured was very friable, and the suture had a strong tendency to cut through."	Ten days after operation two ligatures were removed from the sinus. Patient made a good recovery.
Dr. Ashton, Annals of Gynecology, April, 1890.	Jan. 1888, abscess of right ovary and tube.	.....	Yes.	Track of drainage tube did not close. October, 1888, second section resulted in finding one ligature after flushing out the abdomen; no drainage, yet a fistula resulted, necessitating a third operation in February, 1889, with complete closure. The following August, however, the fistula reopened and discharged a ligature.	
Dr. B. F. Baer, personal communication.	Ovariotomy.	Chinese twisted figure of-8.	Yes, for two days; tube cleaned with syringe every half hour.	There were intra-ligamentary adhesions to descending colon and small intestine; fæcal fistula resulted.	Fæcal fistula caused by thinning of bowel and the drainage tube. Ligature came away two weeks after operation.
Dr. J. M. Baldy, personal communication.	Ectopic gestation; local peritonitis.	Twisted silk, figure-of-8.	Yes, 8 to 12 days; tube cleaned with syringe every hour.	Intestinal adhesions, beginning gangrene of sac, fistula at site of drainage-tube, refused to heal by usual methods.	Ligature came away thirteen weeks after operation, fistula healed spontaneously.
Dr. H. Beates, Jr., 4 cases, personal communication	Salpingitis.	Twisted silk No. 3, Staffordshire.	Yes, 1 to 2 days; injections of bichloride (1 : 10,000) cotton capillary dressing.	General adhesions.	Fistula at site of drainage-tube. Ligature came away in twelve weeks, healed.
Dr. Beates has had three cases of fistulæ from other operators, in which "fishing out" resulted in a cure.	Pyosalpinx.	Same.	Same as above.	General adhesions; patient in bed five weeks.	Fistula. Ligature came away in eleven weeks; healed.
	Pyosalpinx.	Same as above.	Same as above.	General adhesions; patient in bed five weeks.	Ligature came away in fourteen months.
Ligatures, twisted No. 4 in one, smaller in two.	Ovariotomy; multilocular cyst.	Same as above.	Same as above.	No complications.	Ligature expelled through abdominal fistula in ten weeks.
Dr. Hannah T. Croasdale, personal communication.	Removal of tube and ovary of one side; local peritonitis.	Cable twist No. 3, Staffordshire knot.	8 hours.	Extensive adhesions prevented removal of appendages of other side.	Patient in bed from June 2d to February 9th. Ligature discharged January 31st; rapid improvement afterward, the wound entirely healed February 4th.
Dr. Joseph Hoffman, 2 cases, personal communication.	Pyosalpinx.	Chinese twisted No. 3, figure-of-8.	Yes; tube cleaned with syringe at short intervals.	General intestinal adhesions; local peritonitis.	Ligature discharged in about three months. Patient remained in bed six weeks.
One case from his practice, the other under observation.	Pyosalpinx.	Same.	Yes.	General intestinal adhesions; general peritonitis, pus.	Ligature discharged in about three months. Patient in bed two months.
Dr. H. A. Kelly, reported in the British Gynecological Society, by F. B. Jessett, October 23, 1889.	Left ovarian dermoid cyst.	Chinese silk.	.....	Dr. Kelly reports that "in her convalescence she had a large ante uterine hæmatocele which is slowly undergoing contraction."	Mr F. B. Jessett finds, five months after operation, an abscess in the anterior wall of the vagina, opens, drains, and finds a Chinese silk double ligature. Negative history regarding rigors and high temperature.

Operator.	Operation.	Ligature.	Drainage.	Remarks.	History of Fistulæ.
Dr D. Longaker, personal communication.	Hydrosalpinx, puerperal; local peritonitis.	Plaited silk medium size, figure-of-8,	Yes; 36 hours	Extensive adhesions; sinus following drainage track.	After a few months one ligature was thrown off; at the end of the sixth month the second came away. Fistula failed to heal for one year; was finally curetted and injected with nitrate of silver and healed.
Dr. Charles B. Penrose, personal communication.	.....	Twisted silk No. 3, figure-of-8.	.....	.....	Has had two cases in which a sinus lasted several months: one due to syphilis, the other to tuberculosis. Never had a case of discharged ligatures in abdominal section,
Dr. Wm. Goodell, reports in the Phila. Obst. Soc., March 7, 1889, the following 3 cases.	Removal of intra-ligamentary cyst.	.....	.....	Compelled to re-open wound for bleeding; five days after a fistula resulted.	One and a half years after operation fistula still remains; the only annoyance to the patient is an escape of gas.
	Pelvic abscess.	.....	Prolonged.	A counter-opening may yet be necessary per vaginam.	Fistula caused by the prolonged use of the drainage-tube.
	Recurrent intra-ligmentary cyst lying in a large abscess cavity.	.....	Yes.	Fistula resulted from a previous operation in which a clamp had been used many years ago.	Fistula still present at the time of the report; was then trying to heal with iodine applications along the entire track.
Dr. B. C. Hirst, 2 cases, personal communication.	Pyosalpinx.	Twisted silk, figure-of-8.	No.	Patient was easily managed; out of bed three weeks. Excessive hæmorrhage necessitated passing two strong ligatures at the base of the right broad ligament	Fistula of a year's standing. After discharge of ligatures, fistula healed.
	Removal of former stump one-quarter ovary, and four ligatures	.....	.....	The ligatures were not surrounded by lymph; accessible to sight and touch. Pain, which had followed previous operation, disappeared after their removal.	
Dr. John B. Deaver, 2 cases, personal communication.	Double pyosalpinx.	Twisted silk, figure-of-8.	Yes.	Many adhesions.	Fistula at site of tube track. Ligature was expelled four weeks after operation.
	Ovariotomy for large multilocular purulent cyst.	.....	Yes.	Patient had been tapped a number of times, making dense adhesions.	Fistula in tube track. Ligature was expelled six weeks after operation.

medium size. A Staffordshire knot was used. Drainage for five days; recovery good. With the exception of an occasional pain in the region of the stump the patient was well and attended to her household duties. Fifteen months later, however, the patient brought the ligature, claiming to have discharged it from the urethra after much tenesmus at micturition. She gave a history of much previous pain over the right side of the bladder and frequent desire to urinate. Examination showed slight tenderness of stump and a tendinous cord leading to bladder. After a few weeks all tenderness disappeared and the patient was well.

CASE II.—Operation in May, 1887, by Dr. R. S. Hunt. I was present at the operation. There was a cyst of the left broad ligament. The ligature was braided silk, No. 9, tied in a Staffordshire knot; no drainage. Aside from several stitch abscesses recovery was good, and patient was up in four weeks.

During the latter part of August of the same year the patient experienced great pain in the scar, shooting toward the right side. A small abscess formed in the scar, was lanced, washed, probed, and found to extend down toward the stump. In about two weeks the ligature was expelled, and in a short time all had healed.

The first case presents two factors, each of which may account for the discharge of the ligature. First, the friable condition of the cyst-wall, part of which helped to form the stump, the surrounding tissues from want of vitality failing to encapsulate or absorb the ligature. Second, the length of time the drainage-tube was left *in situ*, owing to my inexperience, this being my first case in which drainage was used. I left it in long enough to become an irritant, and had some difficulty in healing the track.

The trouble in the second case was undoubtedly due to the size of the ligature: the tumor being small and the pedicle in consequence short, the ligature slipped over the button the moment shrinkage of the stump took place.

In connection with this subject I have endeavored to collect as many cases as possible, with a brief history of each. It is only by concentrating our forces that we are able to win the battle, hence the study of cause and effect becomes most necessary.

Dr. Thomas Keith, in his little book entitled *Contributions to the Surgical Treatment of Tumors of the*

Abdomen, relates his experience with catgut ligatures. He says:[1]

"Twice I have had hæmorrhage happen in ovariotomy, and on both occasions catgut ligatures were used; in one some thick catgut ligatures had been used on very thick omentum. Several of the knots came away through the wound, and after weeks of horrible suffering from cystitis, a thick knot of catgut, with the loop but little absorbed, was passed by the urethra."

Dr. Matthew D. Mann tells us in his report of 160 abdominal sections[2] that fistulæ are due either to an abscess in the pelvis from some foreign substance, or the use of the drainage-tube, and he cites an experience in which a fistula resisted all attempts at healing for four years. He is confident that this case was due to a silk ligature. This induced him to use catgut, which proved more satisfactory. Indeed, he feels so sure of its harmlessness that he was comparatively at ease when he found a fistula and discharge of pus follow the use of the drainage-tube, knowing that there was no infected silk at the bottom of the sinus. Later, two knots of catgut came out of the sinus, after which it readily closed.

In a communication from Dr. H. A. Kelly he writes the following:

"I have had a number of cases in which the ligatures have all been cast off through the abdominal walls. In one case of hydrosalpinx and ovarian tumor, the patient afterward had a cellulitis. This suppurated and was drained through the vagina and the ligature discharged. It has frequently happened in cases of pyosalpinx, where long-continued drainage was necessary. I have observed it very constantly in cases in which the pyosalpinx has already ruptured, or been on the point of rupturing into the bowel, these cases always requiring prolonged drainage.

"Ligatures of twisted silk, doubled figure-of-eight, were used. These have been cast off from two months to a year after operation. I never use heavy strands of gut, as there is considerable doubt as to our ability to disinfect them satisfactorily. In all cases there has been drainage from four to five days. I clean the tube at intervals not longer than twelve hours. No sort of antiseptic injections are ever used in any of my abdominal sections."

Dr. Kelly's remark regarding the use of heavy strands of catgut seems of importance. We are never sure of healthy membrane, hence in spite of antiseptic precautions we may often use septic gut. Dr. Matthew D. Mann's statement that gut shrinks one-tenth its length when wet with water should be considered in tying, since too much pressure may cause some necrosis of the stump.

The causes of fistulæ may be summarized as follows: (1) Adhesion to the bowel which, in being loosened, may cause thinning and subsequent sloughing. (2) Heavy ligatures on small stumps. (3) Ends of ligature left too long. (4) Ligatures not thoroughly aseptic. (5) Part of the stump consisting of unhealthy tissue. (6) Prolonged use of the drainage-tube, which may cause localized inflammation, resulting in abscess of the stump or surrounding tissue.

Drainage, however, seems too valuable an aid to discard lightly, for we may meet with serious difficulties in closing the abdomen where there is danger of oozing of blood, which may accumulate and decompose, giving rise to troublesome secondary symptoms.

Among the secondary adhesions most commonly found may be mentioned omental and intestinal adhesions with the stump or abdominal incision as a focus. Such a case was reported by E. Sinclair Stevenson before the British Gynecological Society, April 24, 1889. In this case intestinal obstruction called for a second operation, the omentum was found twisted like a loose rope, dipping into the abdominal cavity, glued to coils of intestine, and its extremity firmly attached to a deeply-seated coil. The importance of carefully inspecting torn surfaces of omentum or peritoneum and obviating adhesions by stitch or removal, spreading out the omentum toward the left just before tying the abdominal sutures, becomes at once manifest.

Omentum caught in the holes of the drainage-tube, is another unpleasant complication, but can be avoided by using tubes of small calibre with small perforations, as advocated by Dr. Joseph Price.

Intestinal adhesions to the stump or to surfaces of torn adhesions are best overcome by free purgation and the avoidance of opium.

Painful stumps may be due to an uncovered ligature, to unhealthy tissue left in the stump, or, as Dr. B. C. Hirst has shown us, by too much ligature and an unfinished operation.

This brings us to the last point of importance, namely, unfinished operations. With this I had an unpleasant experience in two cases some years ago, and have profited by it. In one case a pus-tube was so tightly adherent to the pelvic walls and uterus that my courage failed me, and contenting myself with removal from one side I closed the abdomen. Three months later my patient had a sharp attack of septic peritonitis, and she died five months after this, her abdomen literally filled with multiple abscesses. The second unfinished case was of a similar nature, though not so far advanced; the adhesions again intimidated me; the patient recovered promptly, and in spite of hot July weather was temporarily relieved. The following winter I was called to treat a localized peritonitis on the side where I left the pus-tube. She recovered, but has since passed out of my hands. I have learned that to open an abdomen and leave pus there, is as harmful as to know of the presence of pus and not

[1] On page 17.

[2] Buffalo Medical and Surgical Journal, April, 1890.

attempt its removal. I have since endeavored to remove the cause of sepsis, even though the ideal operation was out of the question, and the results have been more satisfactory.

This leads me to an important question which has agitated my mind of late, and which is best illustrated by a brief account of two cases from my practice, both unilateral hydrosalpinx. In both I removed the affected tube and ovary—one in March, 1887, the other in February, 1888, the remaining appendages being apparently normal. Both recovered promptly and improved in health. But in each the former symptoms returned on the other side in eighteen and six months respectively.

The first case reported again three months ago, and I found a painful mass on right side. She at once made preparations for a second operation, which was performed in March, 1890. Some omental adhesions to the incision were found; the tube and ovary were adherent and cystic; the stump was healthy. Patient recovered promptly, and it is now seven weeks since the operation; no pelvic pains; intestinal functions normal.

In the second case operation was performed on May 9, 1890. There were omental adhesions to the abdominal wall and intestinal adhesions to the stump. The uterus, abdominal wall, ovary, and tube were adherent. There was decided constriction of the tube near the ostium internum. I removed the tube and cystic ovary and separated all adhesions except those to the stump.

May 18. Patient doing well.

This leads to the question: Is it the proper course to remove an apparently normal ovary and tube when there is hydrosalpinx on one side, or shall we let the patient run the possible risk of a second operation?

Is there the same danger as in pyosalpinx? Should this last question receive an affirmative answer it certainly behooves us to explain such dangers fully to the patient and gain her consent to remove, if necessary, even an apparently healthy ovary and tube, so that she may not be exposed to the dangers of a second operation.

REMARKS ON THOMSEN'S DISEASE, WITH REPORT OF A CASE.[1]

By HAROLD N. MOYER, M.D.,
Professor of Physiology in Rush Medical College, Chicago.

It is scarcely necessary to enter upon an extended consideration of the literature of this subject, as all that was previously known of this disease was admirably summarized in the monograph of Professor Erb, published in the early part of the year 1886.[2] In this article Professor Erb states that he believes the disease to be a tropho-neurosis of the muscles, forming a definite clinical group with characteristic symptoms. In January, 1886, an article by Dr. Allan McLane Hamilton[1] denies this conclusion and states that the peculiar symptom-complex termed Thomsen's disease is frequently found in other diseases, particularly in hystero-organic disorders, and in the third stage of posterior spinal sclerosis, and is by no means uncommonly associated with coarse cerebral lesions. He regards it as in most cases a purely psychic disorder, which depends first upon inhibitory insufficiency, and secondly, upon an unstable emotional state, which interferes with the origin of proper volitional mandates. In support of his views Dr. Hamilton describes several cases, in two of which the symptom of muscle stiffness was present, associated with other nerve lesions. The third case was evidently one of hysteria complicating a fairly well marked case of paralysis agitans.

That the symptom of spasm at the inception of voluntary impulse does not alone constitute Thomsen's disease will hardly be denied, and that it may be occasionally associated with other organic lesions, would seem to be attested by Dr. Hamilton's cases; that it occurs as frequently as he thinks it does, I am inclined to doubt, as it has never come to my notice in a not inconsiderable neurological practice.

Erb divides the cases so far reported into typical, doubtful, and symptomatic. In typical cases the lesion is always confined to the voluntary muscles, begins in early childhood, and probably in many cases is congenital. It is usually hereditary or appears in families with a strong neurotic taint. The majority of cases so far reported have one or more relatives affected with the same disease. The disease is characterized by a peculiar stiffness and cramp in the muscles, which comes on with the inception of voluntary motion and which, after a time, gives way and permits the performance of the contemplated movement. After a certain number of repetitions the movements become easier, and the cramp, which is painless, disappears. The contractions are always increased by cold and mental excitement. The muscles are commonly well developed, and elastic, but they do not contract as strongly as in health. The electrical reactions are changed and, according to Erb, consist in an increase in the excitability of the muscles and a response, normal or diminished, to the stimulation of the nerve, with both currents. The galvanic current gives a qualitative change, in that the ACC is prompter and stronger than CCC. All contractions last several seconds after the stimulus is withdrawn. Erb found in several of his cases considerable hypertrophy of the muscular fibres, with increase in the nuclei, changes in the

finer structure, and a slight increase in the interstitial connective tissue.

While the histories of these cases are sufficiently clear to warrant us in assuming that we have here a pathological entity, yet I am not sure that the disease does not also occur later in life, in the so-called adult forms. It is possible that at least some of these cases can be classed as true examples of the disease, particularly those of Schonfeld's, Seligmüller's and Engel's.

The following is perhaps the most clearly marked of all the adult cases thus far described :

W. H., of Arkansas, aged twenty-five, presented himself in January, 1884. Notes made at that time are as follows: The family history shows that his father died of consumption at the age of thirty-two, and that his mother was killed by an accident at about the same age. The paternal grandparents are still living at an advanced age, and are in good health. Maternal grandfather still living, aged seventy-eight. Maternal grandmother died of erysiplas at an advanced age. Patient is the second child. He has one brother and two sisters living and well. They have never been affected with any disease similar to that of the patient, and no neurotic trouble has ever been observed in the patient's family. He has always had the best of health. Has used tobacco excessively, but alcohol only occasionally and in small quantities. Is married and has one child. There is no evidence of venereal disease. Has worked hard since his seventeenth year as a sailor, fireman and an engineer, and in these occupations was exposed to varying and extreme temperatures.

About two years ago he was employed in a nail factory, and at that time he noticed the first symptoms of his present trouble. The work required him to stand in front of his machine and to make constant and rapid flexion and extension of the forearms, at the same time stepping from side to side. The first symptom noticed was a slight stiffness, first on one side, then on the other. For a time these symptoms would cease only to recur again at varying intervals of from a few days to a couple of weeks, but with ever increasing severity. Finally the patient had to give up his employment, owing to the lessened control over his muscles. When grasping anything it was impossible for him to loosen his hold promptly, and he experienced great uncertainty in attempting to walk, as he was likely to fall on his face owing to the flexion of the legs. He now rises very slowly from the chair, and walks with a hesitating gait until he has taken a few strides. The contractions often persist for ten or fifteen seconds, and are always aggravated by cold and mental excitement. The patient has a fine physique and the muscles are exceptionally well developed; indeed, from their volume and firmness he would be considered quite an athlete. The peculiar condition is absent on rising in the morning, but after he he has been up for a few minutes the contractions begin and seem to increase until after working a few hours, when they decrease. Since changing his work to that of a night watchman, the disease has not been so severe. All the nervous functions except motility are perfectly intact. The reflexes are normal, and the patient eats and sleeps well and has not the slightest pain. The muscles of the face and of mastication are intact. The voice and mental characteristics are unchanged. Electrical excitation of the muscles is followed by a long contraction which persists some seconds after the current is broken. The qualitative reactions described by Erb had not at that time been pointed out, but it is possible that they might have been found had they been looked for. The size and appearance of the muscles also indicated that the peculiar muscular changes had come on; and while they appeared strong, they were not actually so, as their voluntary contractions were much weaker than would be expected.

The fact mentioned by this patient that immediately after leaving the bed in the morning he gets about much more easily than later in the day, was also observed in one of the typical cases described by Bernhardt.[1]

While we cannot draw definite conclusions from a single case, yet the history of this patient teaches that Thomsen's disease may occur in adults without special neurotic heredity, and from causes competent to produce other forms of nervous disorder.

Unfortunately, this individual was only a short time under observation. All possible means have been used to learn his subsequent history, but thus far without success.

MEDICAL PROGRESS.

The Treatment of Injuries of the Urethra.—Dr. Haegler has made a series of experiments on dogs to elucidate the proper method of dealing with wounds of the urethra (*Deutsche Zeitschrift f. Chirurgie*). His conclusions are as follows:

1. After extensive rupture of the urethra external urethrotomy should be done at once, and the ends of the torn urethra sutured. The edges of the wound cannot, however, be always closely united.

2. The suture should be introduced as far as possible into the submucous tissue, and during the first twenty-four or forty-eight hours a catheter should remain in the urethra, the perineal wound being open.

3. Bougies should not be used until the wound has completely healed.—*Annals of Surgery*, July, 1890.

Rhinoscleroma.—Wolkowitsch denies rhinoscleroma as a disease localized in the mucous membrane of the nose and surrounding skin, characterized by hard proliferations, by an exceedingly chronic course, and by being absolutely incurable (*Centralblatt f. Chirurgie*, June 7, 1890). Cases have been reported from Austria, Italy, Russia, Central America, Cairo, Switzerland, and Sweden. The disease begins with few symptoms, most frequently in the nasal cavities, but occasionally in the

[1] Centralblatt für Nervenheilkunde, 1885, p. 124.

fauces and larynx, and one case is reported in which it began on the hard palate. Wherever the disease begins the nasal cavity is soon involved. The macroscopic alterations are the formation of more or less circumscribed nodules, tubercles, and plates, involving the deeper layer of the skin and mucous membrane, and with marked swelling around them. Occasionally the nodes atrophy, the connective tissue contracting in consequence and causing distortion, and sometimes interfering with respiration. The swellings never ulcerate unless antisyphilitic treatment is used. The symptoms are few; pain is almost entirely absent; there are the usual symptoms of nasal catarrh; and if the larynx is involved, dyspnœa may become a prominent and serious symptom. The course of the disease is very slow, lasting in one case for twenty-six years. No treatment save excision of the nodules seems of the slightest use. Histologically the growth consists chiefly of a small-cell infiltrate. Microörganisms resembling the pneumococcus are invariably found.

Treatment of Sciatica and other Neuralgias.—Mordhorst (*Therapeutische Monatshefte*, June, 1890) states that the diagnosis of sciatica is not always easy, and that inflammatory thickening of the rectus femoris and vastus externus may be mistaken for this condition. It may also be confounded with rheumatic affections of the trochanter major and the muscles covering the hip-joint, especially the tensor vaginæ femoris, in the tendon of which may be found small masses varying in size from a lentil to a bean. These may be mistaken for true *punctata dolorosa*, as they are painful upon pressure. In many of these cases the author has found an excess of free uric acid in the urine, and so concludes that these masses are urates deposited in the tissues.

With these few remarks on diagnosis, the author takes up his special methods of treating sciatica, which he has employed for the past four years, and for which he claims the best results. In cases of neuritis—most of these cases belong to that class—it is well, he says, to begin with a hot bath of from fifteen minutes to one hour's duration, followed by rest in bed of at least one hour, after which electric massage is to be used after the author's method. This consists of the application of the cathodal electrode having a surface area of at least 100 square cm. to the sciatic notch, while a revolving cylinder connected with the anode is passed down the limb along the course of the nerves. Deep pressure is made when the electrode is drawn downward, but it should only touch the skin lightly when returned, to prevent a break in the current. The author says that strong currents (from 5 to 10 milliampères) can be used in this manner, with a corresponding rapid absorption of inflammatory exudate.

Of 36 cases of sciatica treated in this way, 30 recovered, and 6 were improved. One case was cured in eight days, but the average length of treatment was from three to six weeks. Of 13 other neuralgias, 10 were cured and 3 improved.—*Journal of the American Medical Association*, July 26, 1890.

Incompatibilities of Antipyrine.—The *American Druggist* gives a list of drugs with which antipyrine is incompatible. Among them are the following: Carbolic acid in strong solution, hydrocyanic acid, nitric acid, tannic acid, iodide of arsenic, chloral, sulphate of copper, decoction and fluid extract of cinchona, sulphate of iron, bichloride of mercury, infusion of uva ursi, solution of potassium permanganate, sodium salicylate (liquefies), spirit of nitrous ether, syrup of iodide of iron, tincture of chloride of iron, tincture of cinchona, tincture of catechu, tincture of iodine, tincture of kino, and tincture of rhubarb.—*Therapeutic Gazette*, July, 1890.

Intestinal Antisepsis.—Cantani believes that the best method of applying antiseptics in the treatment of intestinal diseases is by rectal injection (*Wiener med. Blätter*, No. 22, 1890), experiments having shown that fluids given in this way reach not only the upper part of the intestines, but may even reach the stomach. If necessary, the reservoir may be raised two or three yards above the level of the rectum. If there is fever, the temperature can be reduced by using the solution cold; if collapse, as in cholera, the patient can be stimulated by using the solution warm or hot.

Cantani thinks the best antiseptic to use in this manner is tannic acid, which not only checks the multiplication of bacteria, but destroys the ptomaines. The solution should contain not more than one per cent. of tannic acid. In diarrhœa and dysentery this solution acts not only as a disinfectant, but also as an astringent. In typhoid fever, Mosler has found it very efficient in reducing tympany and checking diarrhœa.—*Medical Chronicle*, July, 1890.

Treatment of Snake-bites.—Professor Kaufmann contributes to the *Revue Scientifique* a paper describing his recent researches and experiments regarding the bites of poisonous snakes. He advises that in the treatment of a bite the injured limb should be tightly bound above the bite, as quickly as possible, with a handkerchief or any other available constrictor, and that then a 1-to-2 solution of chromic acid should be injected deep into the wound, making several similar injections in the neighborhood of the wound. If these directions are carefully followed, the poison will be destroyed before being absorbed. If there is already much swelling of the wound, more injections should be made in various parts of the swelling, which should then be manipulated to bring the acid thoroughly in contact with the poison. The swelling should then be freely lanced and as much as possible of the fluid squeezed out. The skin should be washed with the chromic acid solution, followed by the application of compresses saturated with the solution. If the swelling returns, these procedures should be repeated.

This local treatment should be supplemented by the internal administration of alcoholic stimulants and aqua ammonia. Professor Kaufmann, however, strongly condemns the use of large quantities of alcohol, which, he thinks, paralyze and depress the nervous system.—*Indian Medical Gazette*, May, 1890.

Œdema Pulmonum.—Grossman (*Zeitschrift für klinische Medicine*, Bd. 34, H. 1, 2, 3, 4, 1889; *Wiener klinische Wochenschrift*, April 2, 1889), in his remarkable experiments concerning œdema of the lungs, which have been carried out in the laboratory of Professor v. Basch, in Vienna, has made some important discoveries. An acute

general pulmonary œdema occurs in dogs, and not as hitherto supposed in rabbits alone, from obstruction of the left auricle and compression of the left ventricle. He has learned that the transudation plays but a secondary *rôle* in the causation of the dyspnœa, and that the most important obstruction to respiration is the inflexibility of the lung on account of the œdema. In consequence of the vascular engorgement there occurs an enlargement of the alveolar spaces, that is, an enlargement of the lungs. He considers transudation a factor of no importance in dyspnœa. We not only have congestion and œdema through muscarin intoxication, but also swelling and stiffness of the lungs and bronchial cramps. He thinks that his investigation prove the primary cause of the congestion of the lungs to be the narrowing of the left side of the heart, contrary to the theory of Conberm-Welch, who considers it due to paralysis of the left side of the heart.

Moyer (*Medical Standard*, September, 1889), in a recent discussion in the Chicago Pathological Society, took the stand against the majority of the members regarding the indications for pilocarpine in pulmonary œdema. His views meeting with scant support, he determined to try the drug in the first case that offered, where there were no heart complications or threatened coma. A case recently came under his care presenting these conditions,and the drug was administered with the most happy effect.

Fothergill's Anti-rheumatic Pills.—The late Dr. Fothergill used the following combination in a large proportion of his cases of chronic rheumatism:

R.—Arsenious acid . . .	3 grains.
Powdered guaiac . . .	3 drachms.
Powdered capsicum . .	30 grains.
Pill of aloes and myrrh . .	3 drachms.

Mix, and divide in 120 pills. One pill was ordered three times a day, in connection with a diet rich in fatty foods. Also, a general tonic treatment was in most cases found advisable at the outset.

Treatment of Tympanites.—

R.—Naphthol Carbonate of Magnesia Charcoal	of each 1½ drachms.
Essence of peppermint . .	10 drops.

Make into twelve powders, and take one every two hours until relief is obtained.—*Revue Obstétricale et Gynécologique*, July, 1890.

Creolin for Pruritus Vulvæ.—

Creolin	3 to 5 parts.
Linseed oil	100 parts.

Apply with friction to the affected parts every four or five hours.—*Revue Obstétricale et Gynécologique*, July, 1890.

Formula for the Administration of Creasote in Phthisis.—

R.—Creasote	30 grains.
Rum	1½ ounces.
Syrup of tolu	1 ounce.
Distilled water . . .	2 ounces.

A dessertspoonful twice or thrice a day in a wineglassful of water, to persons having a tubercular tendency.—*L'Union Médicale*, July 5, 1890.

Mercurial Fumigation in Pseudo-membranous Laryngitis.—Dr George E. Law (*Brooklyn Medical Journal*, August, 1890) enthusiastically advocates mercurial fumigations in the treatment of pseudo-membranous laryngitis. His opinions are based on the results of treatment in seven cases, six of which recovered. Of the six, three had diphtheritic membrane in the pharynx in addition to that in the larynx, and paralysis followed in one.

The apparatus used by Dr. Law consists of a tent, and an alcohol lamp with arms to support a piece of sheet-iron. The tent may be improvised by fastening a bed-slat to each post of the child's crib, connecting them by cross-pieces, and throwing a sheet over this frame-work. The lamp is then lighted, and, when the sheet-iron plate is hot, thirty grains of calomel are dropped upon it, and the apparatus quickly placed in the tent. The duration of the fumigation should be about ten minutes. The procedure should be repeated at first every two hours, increasing the intervals as the symptoms diminish. Attendants must be cautioned not to inhale the fumes, as there is danger of mercurial poisoning, though this danger does not seem to exist in patients suffering from pseudo-membranous laryngitis.

Hot Enemata in Typhoid Fever.—Following the suggestion by Professor I. T. Tchüdnovsky, Dr. Theodor K. Geissler, of St. Petersburg (*Vratch*, No. 22, 1890), has undertaken an experimental inquiry into the action of hot enemata on patients suffering from enteric fever. In all, five cases (males, aged from fifteen to twenty-nine years) were selected for the purpose, each experiment lasting eight days, and being divided into two periods of an equal duration, during one of which the patients received daily (at 11 A.M.) an enema of one quart of water at 108.5° F. The essential results of the researches are as follows: (1) Hot enemata manifest a very favorable influence on the intestinal tract in typhoid fever. In cases of diarrhœa, they markedly diminish the frequency of stools and improve their quality, the fæces becoming less fluid. The injections also relieve abdominal pain, and produce a beneficial action on constipation when present. (2) Immediately after an enema, the bodily temperature, as a rule, slightly rises. When examined an hour later, the temperature proves to be the same as, or even lower than, the temperature before the enema. (3) In the long run, the injections seem to promote defervescence, or, at least, the transformation of a continuous fever into a remittent or intermittent one. (4) Immediately after an enema, the frequency of the pulse commonly somewhat decreases, to increase at the end of an hour. At the same time, the pulse becomes firmer and fuller, its dicrotism less pronounced, and the cardiac contractions more vigorous. (5) The respiration usually quickens, but becomes slower in an hour or two. (6) The blood pressure distinctly rises. (7) The daily amount of urine increases, while the specific gravity sinks. (8) The enemata are invariably perfectly well borne, the patients being rather pleased with them, and a sensation of well-being always follows. As a rule, the injection is retained by the patient from twenty to thirty minutes.—*London Medical Recorder*, July, 1890.

DELAYED LABOR FROM PROLAPSE AND OCCLUSION OF THE CERVIX.

A very frequent cause of delay during normal labor is prolongation of the anterior lip of the cervix produced by the presenting part, and its impaction between the head and the symphysis pubis. This minor complication is generally readily detected by the examining finger, and may be remedied by placing the woman upon her side, employing an anæsthetic if her suffering is severe, and, in the intervals between the pains, pushing the head a little upward and backward and carrying the projecting lip above the head with the finger until the commencement of the next pain. A few efforts in this way will generally result in the retraction of the cervix over the head and labor will go on naturally. It is sometimes observed with primiparæ that the cervix becomes excessively distended and that the external os remains very slightly dilated. The cervical tissue may become so thin as to resemble closely the membranes, and we recall a case in which the attending physician punctured this tissue with a probe, supposing that he was rupturing the membranes. In such a case the os uteri will be found near the posterior wall of the pelvis and can usually be dilated by the fingers or by a Barnes' bag.

It occasionally happens, however, that so firm is the tissue about the external os that the cervix containing the head becomes excessively thin, and projects between the woman's thighs. Such a case is described by Jentzer (*Archives de Tocologie*, May, 1890). The patient had been in the care of a midwife, but labor had been delayed. The physician was summoned with the statement that the cervix was dilated and obliterated; that the head was presenting, but that neither the cervix uteri nor the neck of the child above the head could be felt by the examining finger. On examination a tumor as large as the head, reddish in color and containing an opening about a third of an inch in diameter, was found projecting from the vulva. The occiput of the child had descended toward the mother's left side, rotation not having occurred. The patient was anæsthetized, the tissues at the borders of the os uteri were incised and dilatation was rapidly performed by the fingers, and the membranes were ruptured, but the child was found dead. While the midwife made counter-pressure upon the sides of the cervix, the child was delivered by traction without great difficulty. The cervix was easily replaced. Under antiseptic precautions the patient made an uninterrupted recovery. It is interesting to note that no history or evidence of prolapse occurring during pregnancy, or of endocervicitis, or any inflammatory disorder, could be obtained, and the cause for the complication remained unknown.

Martin, Latz and Auvard have reported similar cases. Quite recently in examining a patient seven months pregnant, we found great elongation of the cervix with prolapse and ulceration. It was necessary to replace the cervix and to maintain its position by antiseptic tampons renewed every second day.

It is not infrequent to find, in women giving a history of specific infection, such deposit of syphilitic tissue about the os and cervix as to make dilatation excessively difficult. In these cases profound anæsthesia, manual dilatation, and elastic dilators may be employed to advantage. As soon as a narrow-bladed forceps can be introduced the head may be brought down and dilatation completed, under anæsthesia, by the forceps. In a case of labor in which the first stage lasted seventy-two hours, it was necessary to complete delivery in this manner, and under antiseptic precautions mother and child recovered well.

Dührssen has recently advocated multiple inci-

sions in the cervix in delayed labor. While this procedure can hardly be thought devoid of danger, yet if caution be exercised to incise in many places but not deeply in any one, and if strict antiseptic precautions be observed, the lives of children can doubtless be saved by this expedient which otherwise must be lost through delay. The tampon of iodoform gauze furnishes a safe and reliable method of checking hæmorrhage should serious bleeding follow such dilatation.

REVIEWS.

Terminologia Medica Polyglotta: A Concise International Dictionary of Medical Terms. Compiled by Theodore Maxwell, M.D. Camb.; B. Sc. Lond.; F.R.C.S. Edin. 8vo., pp. 459. Philadelphia: P. Blakiston, Son & Co., 1890.

This work represents an enormous amount of labor on the part of the compiler and his assistants, comprising, as it does, the French, Latin, English, German, Italian, Spanish, and Russian synonym of every medical term, and it is only owing to an exceedingly ingenious arrangement and the avoidance of descriptive definitions that the volume is not as large as an "Unabridged." French is selected as the key-language, but this fact in no way interferes with the usefulness of the book to a student who cannot read French. Suppose, for example, that an Italian in reading German comes to the word *zunge*, of which he wishes to know the meaning. Turning in this work to *zunge*, he finds the English, *tongue*, and French, *langue*. If, now, he is unfamiliar with the English and French words, he must turn to *langue*, under which he will find the synonyms in six languages, including that of his own. Again, suppose that an Englishman wishes the synonym for the Italian *malattia*. Turning to this word, he finds the English, *disease*, as well as the French, *maladie*, while a Spaniard would have to turn to the French heading, *maladie*, where he would find among the other synonyms his own word, *mal*. In other words, every medical term in seven languages has a separate heading (excepting the Russian, which has no separate headings) with the synonym of at least two other languages; and under the French heading the word is repeated in six languages.

The book is well bound and clearly printed, and, while we believe it will be welcome to a few students of foreign medical literature, and especially to medical editors, the number of physicians who are interested in the language of more than one country besides that of their own is so small, that we doubt if the compiler or publisher will ever be repaid for the labor and expense of preparation.

"*The Lesson in Anatomy.*"—Referring to Rembrandt's celebrated picture, "The Lesson in Anatomy," the *Lancet* describes a curious anatomical error which is certainly not generally known. The pronator radii teres is drawn as if it ran from above downward and *in*ward from the radius to the ulna, instead of downward and *out*ward from the ulna to the radius.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY

Stated Meeting, June 25, 1890.

The President, John B. Roberts, M.D. in the Chair.

Dr. Edward Jackson read a paper entited

THE RECOGNITION OF EYE-STRAIN BY THE GENERAL PRACTITIONER,

in which he dwelt on the futility of attempting to give relief from the symptoms of eye-strain by drugs, though they are frequently persisted in until the patient deserts his so-called medical adviser, and takes his chances with the specialist or the charlatan.

From time to time, he said, efforts have been made by ophthalmologists to secure a more general recognition of eye-strain on the part of the mass of the profession; but usually these efforts consist in a recommendation of some special instrument or procedure of diagnosis, as the refraction ophthalmoscope, or the shadow-test, or a set of trial lenses, reduced in size and price to the supposed needs of the mass of the profession. If it were really necessary to apply such special means of diagnosis in order to recognize the presence of eye-strain, there would be little prospect of its early general recognition. But the condition is frequently recognized by the patient himself, and the ophthalmic surgeon finds in the general rational symptoms sufficient grounds for a provisional diagnosis; and if the mind is clear from preconceived hypotheses as to the causes of the symptoms there is no reason why any one reasonably qualified for practice of general medicine should not be able to make a provisional diagnosis, in the great majority of cases, with sufficient certainty to serve for the basis of further investigation and treatment, without resort to any special method of examination. The speaker did not wish to underestimate the value of the ophthalmoscope to the general practitioner, for he did not regard anyone who is unable to use the ophthalmoscope as properly qualified for general practice, but he meant that inability to measure refraction with the ophthalmoscope is no reason for failing to recognize eye-strain.

The patient suffering from eye-strain comes with a certain history and certain complaints, which, carefully considered by the light of a very moderate knowledge of the subject, usually clearly indicate the cause of the trouble. The symptoms in question are:

(1) *Impairment of vision*, either quite temporary, more prolonged, or permanent. A very characteristic form of temporary impairment of vision is that due to sudden relaxation of the accommodation. This occurs when the ciliary muscle has long been overtaxed, and especially in the latter hours of the day, when the muscle is tired out. The patient notices that the print or other near object on which the attention is fixed suddenly becomes blurred, compelling the cessation of the eye-work. After a moment, however, the power of again focussing the object returns, and work can be resumed. The patient is apt to close his eyes for an instant, and, perhaps, rub them, and then finds the sight again restored. If the eye-work is continued, the failure of ac-

commodation recurs, to again rapidly pass away; and keeping on with the work, these periods of inability to see become more and more frequent, until, finally, they greatly interfere with the continuance of the work or quite prevent it. This form of impairment affects only the vision for near work.

Another form of temporary impairment is that due to spasm of the accommodation; it affects distant vision only, and is noticed chiefly by those whose distant vision is otherwise pretty good. It comes on after prolonged straining of the eye, usually for near vision, and lasts until the eye is rested. It is a valuable danger-signal, and should secure cessation from the work causing it until the symptom has disappeared. Permanent impairment of vision is brought about when eye-strain causes myopia or decided permanent damage of the choroid and retina.

(2) *Headache and aching of the eyes.* Eye-strain should be the first thought suggested by any complaint of headache, for in our day and civilization it is by far the most common cause of that symptom. It enters as a factor into the causation of nearly all headaches not due to pyrexia, toxæmia, or diseases of the brain or its membranes. Often it comes on whenever the eyes are used, and is absent when they have a proper period of rest. Very often a chronological connection between the use of the eye and the occurrence of the headache, although perfectly certain after it has been once observed, was not noted by the patient until his attention was directly called to it. Even when the headache is constant and apparently uninfluenced by variations in the amount of eye-work, it may be due wholly to eye-strain.

In hyperopia in young people the accommodation is in excessive use so long as the eyes are open and the attention fixed on any visible object; and hyperopia is the most common cause of constant headache. Dr. Jackson said that he himself was formerly subject to headache whenever confined to the house, and he believed it was caused by breathing vitiated air, until cured by the correction of his hyperopic astigmatism. Many persons have the same idea as to the causation of the headaches they experience when attending the theatre or other place of public amusement, and which are really due to eye-strain. Others ascribe these headaches, and those experienced in travelling or shopping, to exhaustion. This is nearer the truth, only they commonly have in mind a condition of general exhaustion, whereas it is largely one of local exhaustion of the special nervous apparatus concerned in the act of seeing.

The *location of the aching* is of some significance. Generally it is frontal, often described as beginning in the eye, or just back of the eye, or through the temples. Frequently it extends to the occipital region, and may sometimes be felt principally or wholly in that region. Headache most severe in the vertex or confined to that region is probably not very common from any cause, but from eye-strain it is almost unknown. Often the headache is more severe on one side of the head than the other. Sometimes it is entirely confined to one side, but usually it is bilateral.

Those more or less regularly periodical headaches, known as nervous or sick headaches, migraine, or, when confined to one side of the head, hemicrania, are in many cases caused by eye-strain and relieved by its removal. Attacks of this kind are frequently ushered in by certain interferences with vision and subjective sensations of light, affecting a part or the whole of the visual field, and known as ophthalmic migraine. These visual disturbances are simply a part of the general "nerve-storm," and it is not certain that they especially indicate eye-strain.

(3) *Congestion, irritability, or inflammation of the eyes and their appendages*, should always cause the suspicion of eye-strain. A single attack of this kind has no special significance, but repeated attacks of inflammation, or prolonged congestion or irritability, are exceedingly suggestive of a continuing cause; and the most common cause is eye-strain. Every case of chronic inflammation of the margins of the lids, or of recurring conjunctivitis, or repeated styes, should be carefully investigated for eye-strain. Persons when they begin to feel the effects of loss of accommodation in presbyopia or absolute hyperopia, suffer from repeated attacks of conjunctivitis, which they commonly ascribe to "taking cold in the eye," but which are cut short by use of the appropriate lenses, and which, if unchecked, would tend to establish a chronic catarrhal condition which is a constant discomfort to many elderly people.

Of course, these conditions of ocular congestion and inflammation will be recognized by the usual symptoms of redness, swelling, and itching, smarting, or burning pain. It should be noted that headache and these local inflammatory conditions are not usually presented by the same case. They may co-exist, but, more commonly, if one is decidedly present, the other is absent.

So far nothing has been mentioned of the diagnosis of eye-strain, but only the facts ascertained by questioning the patient, and from simple inspection of the eye. If, now, the physician's office contains—what every general practitioner's office should contain—a card of test-letters for accurately ascertaining the distant vision, and a card of fine print for ascertaining the near point of the eye, additional valuable evidence is easily obtainable. The trial of the distant vision will give indication of any considerable degree of myopia or astigmatism. But it must always be borne in mind that troublesome ametropia may be present without preventing perfect distant vision. The position of the near point, if farther from the patient's eye than his age would indicate, is pretty good evidence of strain of the accommodation. Evidence of strain of the external muscles of the eye, heterophoria, can be obtained by simply getting the patient to keep his eyes fixed on some object, near or distant, and covering one eye; then noting whether the covered eye deviates from its position of fixation, and especially whether it makes a quick movement to return to that position when it is uncovered.

To recapitulate briefly, the common symptoms of eye-strain are:

(1) Certain forms of impairment of vision.

(2) Headache, which is to be studied with reference to the times of its occurrence, and the parts of the head to which the aching is referred.

(3) Chronic or repeatedly recurring congestion or inflammation of the eye or its appendages.

And if to these symptoms are added the results of the simple tests of near and distant vision, and the evidence

of tendency of the eyes to deviate from their normal position when covered, a very good basis is furnished for the probable or provisional diagnosis of eye-strain, without recourse to any special apparatus or unusual diagnostic procedure. And in view of these facts there is no justification for the general practitioner who fails to recognize most of the numerous cases of eye-strain with which he is brought in contact.

In the discussion which followed, Dr. George M. Gould referred to other symptoms the result of eye-strain; namely, sleepiness after persistent reading; anorexia and dyspeptic symptoms; nervousness, choreic movements, and even true chorea, and car-sickness when travelling. All of these symptoms he has observed in his practice. With reference to testing the eyes by the general practitioner, he suggested the following simple plan: Have two test-cards, so that the patient will not learn and remember the letters. Let the physician first test distant vision with one of the test-cards; then instil homatropine. This will give perfect paralysis in three-quarters of an hour. Then retest with the other card. If vision has decreased, there is eye-strain, due to astigmatism or hypermetropia. Another practical point is, that if the patient is suffering with headache, he will be relieved by the application of the mydriatic.

Dr. Mary E. Allen asked if, in these cases, the condition of the recti muscles has not something to do with the symptoms. In her own case she had suffered from eye-strain for a long time, with insufficiency of the recti muscles. She frequently had a feeling as though a blow had been struck against the eye. Her explanation of this was that, by a spasmodic contraction of the straight muscles, the elastic eyeball was suddenly drawn with force against the back of the orbit, giving the sensation of a blow.

In closing the discussion, Dr. Jackson said that his paper simply dealt with the *recognition* of eye-strain, and that he purposely considered only those symptoms most generally present, and had in mind the great mass of cases, not the exceptional ones, which, though in the aggregate many, still are proportionally few.

In his experience, myopia sometimes caused severe eye-strain. There is also the strain of convergence, and any inequality between the two eyes in the amount of myopia—and myopia is usually unequal—is very likely to cause eye-strain. The discovery of myopia should not, he thought, rule out the existence of eye-strain.

CORRESPONDENCE.

MEDICAL LAW IN THE STATE OF WASHINGTON.

To the Editor of The Medical News,

Sir: The subject of medical legislation is one that has been considered, more or less, by all of our States, and when the framers of the Constitution of the new State of Washington met they designated as one subject for special legislation the practice of medicine. But before that there was a Territorial enactment to the effect that a physician, before entering practice, must register his diploma with the county auditor; or, if he had been practising for five years before the passage of the law, he should make a statement of the fact to the auditor in writing. This law became a dead letter, as no one paid any attention to its enforcement. As to all new and promising countries, a large flock of all kinds of quacks and itinerants came here.

When the Legislature of the new State met, a bill, known here as the "Powers bill," was introduced, which virtually left all in the hands of a board to be appointed by the Governor. But the bill provided that the board should be chosen from the ranks of the regular profession only, which was considered by the homœopaths, who are about one-eighth of the entire number of medical men in the State, a manifest injustice. After the passage of the bill, the Governor returned it with his veto attached.

Another bill, leaving out the objectionable features, was prepared, and provided that all persons, before practising medicine here, should be examined and licensed by a State board. The meetings of this board are held every six months only—July 1st and January 1st—and no provision is made whereby one entering the State between examinations can practise; he must wait for periods varying from one to six months.

According to his previously announced intention of giving the regular profession a minority representation, the Governor appointed on the board four regular practitioners, three homœopaths, a "physio-medic," and an eclectic. It was no more than was to be anticipated that a portion of the board should be composed of homœopaths, but now the profession consider that a burning insult has been committed against them in the appointment of a "physio-medic." It is difficult to learn what that class of men represents, and no one here knows. At the board meeting a homœopath was elected president, and, without reference to his medical beliefs, it must be said that a better president could not have been found. Although the proceedings of the board were conducted in harmony, the hearts of the "regulars" burned with a feeling of disgust, while the "irregulars" were, of course, well satisfied. With a little stratagem the latter gained their point, by a combine with the "physio-medic" and eclectic members, which enabled them to elect their candidate president of the board, and to place such other members as they pleased in office. The whole scheme was "cut and dried" before the board met, and the opening of the session was delayed so that the "irregulars" could perfect their plans.

The board adopted rules to the effect that a general average of 65 must be made by all but old graduates (of at least five years' standing), who need not average as high in chemistry, physiology, or anatomy as graduates of less than five years' standing. At this meeting each man was given subjects to prepare questions upon.

The examinations were held July 1, 1890, at Walla Walla, when ten men presented themselves, among them your correspondent; and but one man, a homœopathist who graduated in March of this year, failed. The examination was entirely a written one, and was a perfectly fair test of our medical knowledge. There were one hundred and fifty-six questions—viz.: five each on Diseases of the Eye and Ear; ten each on Medical Jurisprudence, Surgery, Histology, Preventive Medicine, Practice, Diseases of the Nervous System, Anatomy, Materia Medica and Therapeutics, Diseases of Women, and Diseases of Children. On Obstetrics there were eleven

questions; on Chemistry fifteen, and on Physiology twenty. On Materia Medica there were two sets of questions, one for the homœopaths and one for the regular practitioners, and the other schools would have had the same privilege had any candidates applied. Two days were consumed in this work.

Laying aside all prejudices, a perusal of some of the questions of the "physio-medic" and eclectic members will show the injustice of having men of that class on the board. During the examination the writer carefully copied the questions, and, in some instances, the spelling—for the question-sheets came to us in the handwriting of the members by whom they had been prepared. The "physio-medic" asked, "What is *pertusses?*" and also the very comprehensive question, "What does delayed dentition prognosticate?" To this last I could not answer, nor could the two or three members of the board, to whom I afterward repeated the question. In Diseases of Women he questioned upon "*leucarrhœa*," "*amenarrhœa*," and "*dysmenarrhœa*." Other questions of his were, "Define *mamary absess*," and "What is pelvic *absess?*" while the last question was upon "lacerated *peroneum*."

The eclectic prepared questions on anatomy and physiology, one of which read as follows: "Name the divisions of the abdominal *aorta*, large branches, and from where *does* the lower extremities derive *there* blood-supply?" Another asked, "What 's the *peremtory* condition of pepsin in the stomach?" to which we afterward discovered he wished us to answer "Hydrochloric acid." Another question was, "What 's the effect of *too much* red corpuscles in the blood?"

Under the heading of Preventive Medicine, in the list of questions prepared by a homœopath, we found two as follows: "What means would you take to resuscitate from an overdose of chloroform?" and "How would you treat a case of poisoning from opium or morphia?" He evidently looks at the subject broadly, and thinks that any means of preventing death should be placed under the head of preventive medicine.

The examination, as a whole, was rigid, and a good test of a man's ability to practise medicine. I was recently informed by a member of the board that the examinations would be made still more severe.

Of all classes of practitioners we have a superabundance, and had the Legislature framed this law so that all men practising medicine in the State of Washington at the time of the passage of this act must come up for examination, the effect would have been excellent.

When I first came to Seattle, a place of 35,000 people, I was told that there were two hundred and fifty physicians here, which is about twice as many as the actual number. Both here and in Tacoma some homœopaths have the largest practice.

It seemed to me ridiculous that we should be required to go before a board in which the representation of the so-called schools was so unequal, but still more when I read the list of questions of the "physio-medic."

There is a class who refuse to pay attention to this law, and another class who were here in sufficient time to register, but neglected to do so, and are inclined to cause trouble.

Seattle, Washington

NEWS ITEMS.

Surgeon Parke on Vaccination.—At the great banquet of welcome given in London to Surgeon Parke, he briefly referred to the inestimable benefit of vaccination. Before the expedition started for Africa he vaccinated nearly every man in Stanley's little army, with the result that when they were surrounded by smallpox there were only four cases among the members of the expedition, none of which proved fatal. But among the camp-followers and irregulars, who had not been vaccinated, smallpox was almost universal, and large numbers of them died. It is probable that, without the precaution of vaccination, the expedition would never have had strength to complete the march across Africa.

A New Method of Advertising.—According to the *Boston Medical and Surgical Journal*, for some time past complaints have made to the Health Commissioners of Brooklyn, New York, of the persistence with which mothers of very young infants are besieged by agents of the manufacturers of infant-foods. Most of the complainants were physicians who said that they had been requested by their patients to take measures to prevent the annoyance. Investigation resulted in the discovery that one of the clerks of the Bureau of Vital Statistics had been communicating the name and address to the manufacturers of the infant-foods, of every recently confined woman. The clerk was, of course, well paid for his information.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 5 TO AUGUST 11, 1890.

By direction of the Acting Secretary of War, William Stephenson, *Captain and Assistant Surgeon*, now on duty at Columbus Barracks, Ohio, is assigned to temporary duty at Jefferson Barracks, Missouri, during the absence on leave of Daniel G. Caldwell, Major and Surgeon, and will report accordingly. On the return to duty of Major Caldwell, Captain Stephenson will rejoin his proper station.—Par. 2, *S. O. 176, A. G. O., Washington, D. C.*, July 30, 1890.

By direction of the Acting Secretary of War, leave of absence for one month and fifteen days, to take effect about August 15, 1890, is granted to Daniel G. Caldwell, *Major and Surgeon*.—Par. 1, *S. O. 176, A. G. O., Washington, D. C.*, July 30, 1890.

By direction of the Secretary of War, the ordinary leave of absence granted to James P. Kimball, *Major and Surgeon*, in S. O. 152, July 1, 1890, from this office, is changed to leave of absence on surgeon's certificate of disability, with permission to leave the Division of the Missouri.—Par. 7, *S. O. 182, A. G. O.*, August 6, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 9, 1890.

Wales, P. S., *Medical Director.*—Ordered in charge of the Museum of Hygiene, Washington, D. C.

Bright, George A., *Surgeon.*—Ordered to the U. S. S. "Constellation."

Mackie, B. S., *Surgeon.*—Detached from the U. S. S. "Constellation," and ordered to Naval Hospital, Philadelphia, for medical treatment.

Derr, E. Z., *Surgeon.*—Ordered to the U. S. S. "Minnesota."

Waggener, J. R., *Surgeon.*—Detached from the U. S. S. "Minnesota," and ordered to the U. S. S. "Kearsarge."

Moore, A. M., *Surgeon.*—Detached from the U. S. S. "Kearsarge," and granted three months' sick-leave.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, AUGUST 23, 1890. No. 8.

ORIGINAL ADDRESS.

THE RELATION OF EYE-STRAIN TO GENERAL MEDICINE.[1]

BY GEORGE M. GOULD, M.D.,

OPHTHALMIC SURGEON TO THE PHILADELPHIA HOSPITAL.

LADIES AND GENTLEMEN: In response to your kind invitation to speak to you concerning some of the relations of Ophthalmology to general medicine, I have chosen one aspect of the subject that is at once most neglected, least understood, and important—to me, indeed, the most important. Other subjects may be more interesting, promise more brilliancy of treatment, or illustrate better one's special knowledge, but in your practice you will have a hundred cases of eye-strain to one of optic neuritis; a hundred of anorexia and malassimilation due to ametropia, to one of contraction of the field of vision; a hundred of nervousness and hysteria to one of hemianopsia or albuminuric retinitis. Moreover, without special training you will not be able to diagnose pathological changes in the fundus of the eye, whilst the recognition of an irritational eye-strain is relatively an easy task.

The essence of what I shall say to you to-night will consist simply in pointing out a few classes of patients, to whom, if you do your duty, you will say, "Go to the oculist." Upon my part this may seem to you a bit of somewhat cunningly selfish advice; but I protest that the matter has certain very unselfish phases, and must, by both of us, be taken very seriously. I have, truly, had in my practice hundreds of patients who have had years, and even a life of daily anguish, because their physicians had not known enough to give them this advice.

The moral of my sermon, therefore, is that eye-strain is an enormously frequent, fertile, and unsuspected source of non-ocular disease. I beg of you not to let any long-eared prejudice blind you to this fact. Fact it is, and he who soonest recognizes it will do himself the more honor and the world the more good. I purpose speaking directly and solely from my own experience, and no fact has been so frequently and emphatically borne in upon me by every day's practice as that eye-strain is a great promoter and producer, first of functional systemic disease, and even, finally, indirectly of organic disease. And the correlate of that truth is this other, that the general physician makes no more frequent and bitter mistake than his indifference to or ignorance of it. To help you to avoid such errors let us try to answer these questions:

1. What is eye-strain?
2. What is its etiology?
3. How is it diagnosed?
4. What are its effects?

This is in accordance with the wise, old advice, that prior to curing an evil we must know its nature, cause, extent, and results.

The term eye-strain is usually applied to the irritational incoördinations and abnormal exertions of the intra-ocular or extra-ocular muscles. The function of the eye is to form a perfect image of an object upon the retina in precisely the same way as a photographic camera does upon the sensitive plate. Strain arises when the eyeball is abnormally long, short, or curved, or when the muscles are not dynamically balanced. The term may be applied to the results of abusive use of the perfect eye, but that is not the common meaning. As defined above, the words need two criticisms. The first relates to an extension of the meaning so as to include nervous and centrally located phenomena. As commonly used the emphasis—indeed, the sole thought—concerns the muscles. But, the simple muscular overuse or strain is, if not entirely absent, at least often, and, I doubt not, generally, a small factor. Where else in the body does one find undue muscular exertion producing such effects as are the rule in eye-strain? The nearest analogy of so hard-worked a set of muscles consists of those implicated in scrivener's and piano-player's palsy. But the ciliary muscle is more over-worked than the muscles of the hand, whilst the effects are dissimilar. In other parts of the body you may have exhaustion, paralysis, localized soreness, myositis, etc., but never the mental, cerebral, and distant reflexes that are the rule in eye-strain. This is an indication, proved by other considerations, that the central neural, or cerebral, elements are predominant, and that the muscular element *per se* is subordinate and *post hoc*. Failure to see this has led to the woful error of those extremists who cure all the ills that eyes are heir to by tenotomies—graduate and undergraduate. It is, indeed, a noteworthy fact that the patient complains little or not at all of ocular symptoms. In

[1] An address to the Philadelphia Hospital Medical Society, July 9, 1890.

the greatest eye-strain the patient will heartily aver that the eyes themselves are perfect, and give no trouble. There are no pains, no soreness of muscles, no local symptoms whatever. This is an anomalous and interesting, but genuine, fact. I have partially tried to explain it elsewhere, and must pass it by at this time.

The second criticism refers to the origin of insufficiency, or lack of muscular balance in the external muscles. It is too commonly supposed that this is, as it were, congenital, or a positive cause of eye-strain. But it is certainly usually true that the insufficiency is a mere consequence of the ametropia. Correct the latter, and the muscle equilibrium is generally soon restored. Tenotomy, before a lengthy trial of this procedure, is no less than surgical barbarism. This, indeed, is a corollary of the fact that the insufficiency is a phenomenon of nerve centres and nerve forces, rather than of strengths or strains of muscle fibre. The acknowledged etiology of much insufficiency is the disturbance produced by ametropia of the normal relation between accommodation and convergence. But, this is patently a nervous phenomenon, pure and simple. The muscle chiefly strained in eye-strain, if any, would assuredly be the ciliary muscle. But, despite the Herculean tasks and torsions it often has to undergo, it does not from these causes inflame, is not paralyzed, or weakened, but actually develops *de novo* a new set of fibres, almost a new muscle, called the Müller ring-muscle. Thus, from a variety of considerations we conclude that in eye-strain we have chiefly to do with nervous, not muscular forces. The facts to fix attention upon are dynamic, not static; neurological, not muscular; central, not peripheral.

As to the ametropia that produces eye-strain, it is almost entirely limited to two varieties, hyperopia and astigmatism. Simple myopia, unless widely differing in degree in the two eyes—anisometropia—produces no eye-strain. For other reasons it may be well to correct near-sightedness, but when you are simply trying to establish a differential diagnosis, you may be assured that if your patient is myopic to only a moderate degree, there will be no reflex neurosis for you as a general practitioner to combat. The danger from following this rule consists in the easy and terrible blunder made by opticians every day, of mistaking a so-called spasm of the accommodation, an astigmatism, or even a high degree of hyperopia, for myopia. As general physicians, however, you will not thus ruin eyes, because you will not prescribe spectacles.

Let us now examine more closely the mechanism whereby hyperopia and astigmatism produce eye-strain.

When the eyeball (antero-posteriorly) is too long—or, what amounts to the same thing, when the refracting powers of the ocular media are too strong—the natural focus of the entering light-rays is in front of the retina. This condition constitutes *myopia*, and from the above explanation it becomes evident that there can be no strain, since the effort, if one may so speak, is to reduce strain. There is already too much refraction, and hence there can be no strain by the eye in attempting to overcome the condition. The rays need to be further dispersed, not more gathered together, and it is the greater gathering that requires an expenditure of nerve or muscular force.

When the eyeball is too short (or the media too weak in refractive power) the retina is in front of the natural focus, and the accommodative apparatus is put to an excess of effort to bring the focus forward, so that it shall be upon the retina. This is hyperopia. All good definition, as the photographers say, depends upon an accurate focalization of the rays from an object, whether upon the sensitive plate of the camera or upon the retina. In hyperopia the definition is only obtained by unceasing over-exertion. It is a Sisyphian task. The focus slips back from its proper position with every instant of inattention. When the object is near, as in reading and writing, the need of greater refracting power is increased or multiplied. This is because rays from near objects are more divergent than from more distant ones. Hence the greater strain in this condition, from near work, and the more marked increase of the whole train of pernicious symptoms when the hyperopic eye is forced to undertake it. The eye being naturally hyperopic, the task set for it by civilization becomes the more glaringly contrasted and severe. Upon the principles of American politicians the oculists and opticians should erect the highest statue in the world to the inventor of printing.

Suppose, now, the cornea unsymmetrical, that is, unequally curved in different meridians, like the bowl of a spoon, the rays of the entering beam of light will be brought to a focus more quickly in the more curved meridian, and the retinal image proportionally blurred. This is *astigmatism*, and, of course, may complicate either myopia or hyperopia. If coexisting with hyperopia it produces the greatest strain.

We understand this by remembering that the ciliary muscle is a sphincter muscle, normally acting equally upon all sides by a common innervation. But with astigmatism, this muscle, or the central nervous system controlling it, seeks to neutralize the effects of the corneal asymmetry by unequal contraction, or excessively straining certain fibres in such a way as to cause the lens to react upon the traversing rays, so as to counteract the unequal influence of the corneal asymmetry. This action of the ciliary muscle

is unphysiological, and as is readily seen, productive of a peculiar irritation.

Besides myopia and hyperopia, complicated or not with astigmatism, we may have presbyopia superadded. This consists of a growing inelasticity of the crystalline lens, or failure in the power of accommodation, which, increasing all through life, reaches in emmetropic eyes such a degree, at about forty-five years of age, that the artificial help of biconvex lenses is required for near work. If hyperopia be also present, presbyopia becomes apparent earlier, and proportionally to the amount of such hyperopia. If myopia be present, then presbyopia comes on so much later.

In passing it may be asked why hyperopia and astigmatism, or eye-strain, seems so much more frequent now than formerly. The answer is clear, but apparently contradictory. It is this: hyperopia and astigmatism are probably less common now than ever before, and yet the direct result of these same defects, that is, eye-strain, is immensely more common. The explanation of this paradox is that the eye of animal, savage and child, is naturally hyperopic. Up to the present century the work of the eye has been adapted to the mechanism. But now, printing, schools, cities, sewing and commercialism have suddenly given the eye tasks for which it was never made, or to which it was never habited. The deity of natural selection never foresaw civilization. Great interest attaches to the inquiry how the eye is to react and adapt itself to meet the duty thrust upon it. One fact is evident: when the recognition of the enormous body of ill-results from eye-strain finally succeeds in battering down professional and popular prejudice, spectacles will be almost as common as noses. Nearly every one would be the better, intellectually, morally and physically, from the proper use of proper spectacles. There are extremely few emmetropic eyes. If from his occupation the farmer may be able to do without correction of ametropia, the farmer's child, if he goes to school, will not be able to do so. The greatest good of spectacles will be prophylactic. Thousands all about us are to-day suffering multiform and irremediable injury, directly or indirectly, because of unsuspected eye-strain. The day will sometime come when a conscientious parent will never permit a child, however apparently healthy, to grow to puberty without a scientific examination of the eyes having been made, and repeated at intervals thereafter. The consequences of eye-strain are so subtle, so varied, so remote, so peculiar, so unforseeable, and so harmful, that only by this plan can they be obviated.

How is the existence of hyperopia and astigmatism to be diagnosed—their existence, I say, not their amount? That either exists to a harmful degree is all you desire to know, but knowing this you also know that, until corrected, it is a permanent source of mischief, and that all remedies other than spectacles are palliative or useless. Many plans are advocated, but every one is objectionable. I take it for granted that you will not use the ophthalmoscope. For twenty years the general practitioner has been urged to do so, and for twenty years medical students have bought instruments that they never used after "swinging their shingles to the breeze." I think their advisers gave bad, or at least useless advice. To use an ophthalmoscope properly requires much and continuous practice. The general practitioner soon finds he has not the time nor the patience, and the specialist who can do it better is close at hand. Whether the growth of specialism generally be for good or bad, it is quite certain to grow, and ophthalmology, of all the specialties, has always been pointed to as a model. The wise man accepts and makes the most he can of the inevitable.

Retinoscopy is a popular fad among my brethren: my advice to you is that you would better let *us* make mistakes with it. If you try to rely upon it you will utter either many falshoods or many objurgations—probably both. Proficiency in its use, as in that of the ophthalmoscope, requires special aptitude and training, and I do not believe that it is to be relied on as an accurate method even in the hands of its best friends.

Of many devices I shall recommend but one to you. Get two differently lettered cards of Snellen test-letters for distance, and hang them in your office, in a good light, fifteen or twenty feet from your patient. With every patient complaining of headache, neuralgia, or dyspepsia, with nervous, hysterical, choreic or anæmic symptoms, test accurately by one card, each eye separately, the ability to read. Keep a record of the lines read in each case. Then paralyze the accommodation with a six-grain solution of homatropine. Half a dozen instillations within three-fourths of an hour are sufficient, but it will be better to give the patient the drops, to be used every hour for a day. When he returns in one or two days, if the headache has in the meantime been better or has disappeared, you may be quite sure you have an eye-strain reflex. This, in fact, is the best method of differential diagnosis between headache due to eye-strain and that due to other causes. Since the great majority of all headaches is due to eye-strain it is a point worth bearing in mind. But now, when your patient returns with thoroughly functionless accommodation, you will retest the acuteness of distant vision, using a different test-card, to avoid the error arising from remembrance of the other letters. If this acuteness is markedly less than it was before using the mydri-

atic, that is, if only larger letters can now be read, you are convinced that hyperopia or astigmatism, or both exist. The amount of the defect is roughly estimated by the extent to which the visual acuity has fallen off. If originally normal, *i. e.*, if the twenty-foot line was read with each eye, and after paralysis of the accommodation it remains the same, you have a rare case of emmetropia. If originally subnormal, and after the mydriatic it remains the same, you have simple myopia. If you wish to tell whether the diminished acuity is due to hyperopia or to astigmatism, you can do so roughly by an astigmatic test-card. But this is a dangerous road, and for your purposes, one that you do not have to travel.

This plan seems to me the simplest and easiest of all for ascertaining the existence of eye-strain. It may be relied on absolutely, it demands no special training or superfine observation, no costly instruments or appliances. It tells you precisely what you need and want to know, and with little or no trouble. You should remember to warn your patient of the symptoms of mydriasis. Moreover, do not forget that with patients over fifty years of age, Time, that conquers all things, has pretty effectually paralyzed the accommodation, and other mydriatic is unnecessary. Before this age pathological reflexes have mostly subsided.

There is one aspect of this question that we must not overlook: How much lessened acuity, or how much hyperopia or astigmatism is sufficient to set up eye-strain and pathological reflexes? This depends entirely upon two things, the nature and the occupation of your patient. If the patient be one of civilization's hot-house plants, a neurotic, sensitive, nimble-witted girl, the smallest defect is sufficient to play havoc with such a quivering bundle of nerves. If with such a case there is the slightest falling off of distant acuity under the mydriatic, if the same line of the test-type cannot be read just as easily, pack her off quick!

Between such a case and the rugged, phlegmatic out-of-door-living farmer there are a thousand degrees to tax the best judgment of the best oculist as to what to do. In general the young have less "leeway" than the older, girls and women less than boys and men, the educated less than the uneducated, those doing much reading, writing, sewing, or other near-work, less than those not so busied. A farmer can safely carry for a lifetime five or ten times the defect that a city girl could endure for only a day.

One word more, despite your smile. Never send or allow your patient to be prescribed for by an optician. This disgrace to medicine and sin against humanity should be forbidden by law. Ruined eyes and inexpressible sufferings daily turn up in every oculist's office as the direct result of this execrable habit. If the oculist's fee is frightful, there are in every hospital ophthalmic departments where out-patients may be treated, free of charge, by competent hands.

I fear I have left myself too little space to speak of the essential or vital part of my subject. The heart of the whole matter is as to the effects of eye-strain.

These may be divided into two chief classes, those limited to the eye itself, and those presenting systemic or extra-ocular results. The first class concerns particularly the ophthalmic specialist, but it is well to note them as we pass by. Some of them serve as pointers, or clear indications of the ametropia. In children, especially boys, styes, blepharitis, and conjunctivitis, often mark the deep-seated trouble. The most common ocular symptom is accommodation-failure. The ciliary muscle temporarily relaxes under the strain, and the words of the printed page blur, and run together, and the eyes must be closed for a moment. Such failures occur more frequently if near-work be persisted in, and may be accompanied with conjunctival injection, pains, flow of tears, spasmodic blinking, or "tic" of the lids, face, etc. Among the organic changes produced by eye-strain is myopia. This may sometimes be caused by changes induced by ametropia, whilst insufficiency and strabismus are almost certain proofs of this cause. A still more profound injury is one that I have pointed out to the profession — a chronic macular choroido-retinitis, with pigmentary changes about the posterior pole, lessened visual acuteness, etc. Thus the eye itself may be irremediably injured by uncorrected eye-strain. It is not true that so long as none of the palpable symptoms appear the condition of the eyes may be ignored. Many of these symptoms are so subtle as not to be noticed until the disastrous result is accomplished. It is doubtless true that eye-strain plays an etiological *rôle* in the production of cataract.

Turning now to the more widespread systemic abnormalism and disease produced by eye-strain, we are struck by the awful, discouraging, exasperating slowness with which even the most glaring consequences are ignored, with what intolerable difficulty this knowledge pounds its way through prejudice and ignorance, both lay and professional. Take headache as the best example. The "common people" are to-day more alive to the fact of its true causation than their doctors. Most medical articles on the subject, and books on practice, either ignore the eye-strain or allude to it as a minor factor. The fact, of course, is that it is far more frequently the cause than all others put together. I do not doubt that ninety cases out of one hundred are due to eye-strain In my first series of one thousand refraction cases in private practice a chief complaint in more

than eight hundred was of headache. The failures to cure or greatly relieve were not over half a dozen. Eye-strain headaches, or neuralgias, as they are sometimes called, may usually be diagnosed by the following considerations:

1. The patient, nine times in ten, is a girl or woman.

2. In the great majority of cases the patient locates the pain in the forehead or temples, or says it starts there.

3. If the headache is not continuous it is usually brought on or made worse by near-work—is greater, for example, during the school season than in vacation, during school-hours than holidays, etc.

4. The headache is frequently associated with anorexia, fickleness of appetite, malassimilation, or some other digestional abnormality, all these being common eye-strain reflexes.

Sick-headache, there can be little doubt, is very often, if not generally, due to eye-strain, though it, like any other functional abnormality, may not be quickly curable by stopping the cause after continuance for half a lifetime.

Fits of nausea and vomiting are not infrequently produced, and I have now had six or eight cases of pronounced "car-sickness," which never returned after getting spectacles. I had one patient last week who was intensely sick with vomiting, dizziness, etc., for twenty-four hours following every street-car ride. She walked twenty squares to see me. I sent her home, with paralyzed accommodation, upon the street cars, without a return of the usual effects. One wonders if sea-sickness is not more or less connected with ocular functions. A physician wrote me from the West that he could produce giddiness and nausea in himself by rolling his eyes upward in a peculiar manner. One of my patients can read without trouble while sitting up, but gets sick at his stomach at once if he reads lying down.

But the cerebral evidences of irritation and disorder, however marked and clear, are of less importance than others that strike at the nutrition and welfare of the whole organism. The war must be carried into Africa! *Delenda Carthago!* Despite all disbelief, prejudice, and the smiles of superior wisdom, it is my well-proved and deep-rooted conviction that eye-strain very frequently produces digestive troubles of various kinds, all resulting in malnutrition. Those who ten or twenty years ago preached the ocular origin of headache, encountered the same wall of prejudice as one does now in reference to this aspect. I shall not attempt to explain the mechanism of this reflex neurosis, that of any such reflex is not wholly clear, but it is certainly as easily understood as a metastatic orchitis in mumps. Whether understood or not, if you will bear the fact in mind you may save yourself much vexation and your patient much suffering by testing the eyes of many an anæmic, nervous, dyspeptic girl, whose trouble you cannot account for or cure. I have had very many such patients freshen up at once upon getting spectacles, and in a month or two gain ten or twenty pounds in weight, without any medicine, and after years of other treatment. It seems at first sight the extreme of absurdity to say that anæmia may be due to eye-strain, yet such is the fact, because nothing can shake my conviction that malnutrition may be caused by it, and anæmia is only the consequence of persistent malnutrition. In girls and young women with severe eye-strain, fickle and poor appetite is almost always an emphatic complaint. Their mothers nickname them "pickers." I know well enough the tricks of *post hoc propter hoc* logic, but if such patients return in a month or two with better health patent in every feature, and now eating three meals a day, I trust my conclusions. The iron on their noses in the form of spectacle-frames has done the red blood-corpuscles more good than it would have done in pills.

It is by thus producing continued anorexia and malnutrition that eye-strain may indirectly lay the foundation for other evils that else had not existed. The headache, hyperæsthesia, or nervous exhaustion, brings the organism just to such a degree of weakened vitality that further resistance is impossible, and the upspringing of latent or inherited diseases of many kinds and of differing degrees of fatality is permitted. No lesson is more clear now-a-days than that disease germs find a nidus only where vitality is subnormal.

Two indirect proofs of the power of spectacle lenses to prevent these results are at hand: First, put a pair of spectacles before your normal eyes that will create an eye-strain such as others have without glasses. Headache, dizziness, and vomiting will in a few hours teach a very practical lesson. Second, note this: A spectacle gets broken, and in twenty-four hours the patient returns with a terrible recurrence of the old but long unknown trouble, the headache, the nausea, the unrest, etc. If an astigmatic lens gets bent a small fraction of an inch out of its proper place, there is the same phenomenon. A visit to the optician is all that is needed.

All the reflexes of eye-strain are primarily phenomena of increased nervous action. They are peculiarly central in character, and may perhaps be considered as a struggle of the ocular and optical centres to translate into sensations imperfect retinal stimuli or optic-nerve messages, as well as to react upon the eye itself so as to perfect its function. With hyperopia and astigmatism present this becomes an irritating and harassing labor, disturbs the equilibrium of the cerebral centres, and liberates large excesses and incoördinations of nerve force.

These unregulated discharges overflow the normal outlets, and produce results varying according to the somewhat accidental routes, and the commissural fibres over which the superabundant discharges pour upon centres incapable of resistance. If the phrenic-nerve centre is flooded, the diaphragm is stimulated to excessive action, and vomiting or other disturbance follows. In connection with this I may mention the case of one of my patients, Mrs. G., who had suffered for twenty years with a persistent and harrowing flatulent dyspepsia, for which many physicians had been consulted, and limitless quantities of medicine had been taken. I speak advisedly when I say that the minute proper glasses were applied the frightful eructations and discomfort stopped. If the glasses are left off a minute or two the diaphragm begins its spasmodic action. If the innocent overflooded centres happen to be inhibitory centres the results are in accord with the function of those centres. Possibly the digestive torpor and malassimilation are explainable as an unregulated stimulation of the pneumogastric. I reported a case last year in which violent rapidity of the heart's action came on with outrageous abuse of hyperopic eyes, and persisted despite all treatment until correcting spectacles were found, then suddenly subsided. Another noteworthy illustration was that of Miss U., who had suffered from periods of aphonia for years. The mydriatic brought the voice back, and the glasses have assured the cure. I have had several cases of non-appearance of menstruation, amenorrhœa, and dysmenorrhœa, in which the proper function was established at once upon the use of spectacles. Two patients had periods of partial paralysis and anæsthesia of the limbs prior to coming to me. These instances of derouted reflex action are characterized by appearing at more or less regularly recurring periods with increasing headache and sometimes with "blind-spells," or other ocular symptoms.

Generally speaking, the excess of irritational stimulus results in positive overstimulation of motor centres. In a large class it will manifest itself as a diffuse abnormal activity. The child or young person is simply "nervous," restive, cannot keep still, will not stick to studies, etc. If the derouted reflex take more specialized channels certain muscles or groups are acted upon, and simple chorea follows. One girl wore out the right shoe in a few weeks by excessive scraping of the foot. A boy was always snuffing or making grimaces with the lips. Tics of the cheek muscles and jerking of the hand or arm are also met with. I have had quite a number of cases of pronounced chorea cured at once by correction of ametropia. I have had no experience with epilepsy or insanity. If I had a case of *petit mal* I would try prolonged mydriasis. Very frequent symptoms of eye-strain are insomnia and night-terrors. The child rolls, cries out in its sleep with fright. The surcharged cerebral centres after the day's warfare are for a long time unable to reach a condition of normal equilibrium. I have more than half a belief that enuresis may sometimes be traceable to the same irritation.

It may be thought that the reports of many of such cases as the above are to suffer revision in the light of one error common to all—hysteria. The old pianoforte tuners swept all the discords into one octave that was called *the devil*, and this was avoided as much as possible in playing. There was a time when, whatever was not understood, or not easily curable in female nervous disease, was called hysteria. It was a convenient cover for professional failure in therapeutics. I have no doubt that many, very many such cases needed, and still need, a pair of proper spectacles, instead of sneers and pilulæ asafœtidæ.

One final illustration and I have done. The common-school system as now carried on is largely responsible for a deal of suffering such as I have described. Children are forced to needless and unhealthful study, and manufactured into sorry examples of intellectual *pâte de foie gras*, namby-pamby mimics and memorizers when they should be in training to make of them healthy young animals. Under this system of over-pressure and sham education the civilized eye, like many another product of civilization, is a poor and pitiable thing. Its little possessor, sadly unconscious of what is the matter, goes on with high pressure, and ambition, and tonics, until one after another the strings of life snap under the high tension. If not so, he finds study becoming irksome, and the parents grieve as they painfully watch intellectual capacity slowly and persistently renounced and life shunted into the world's humdrum and routine. Eye-strain has thus derouted many a natural genius, subtly turning him from intellectual culture to physical but less painful outlets for his activity.

The multiformity and apparent exaggeration of the effects of eye-strain indicated above may seem less extravagant if we remember how vital the function of vision is to every act, how necessary to every minute's safety of the organism, how uninterruptedly active during every instant of waking life. Not only every act, but every emotion and thought—intellect itself, and imagination, are born of or bound up with visual acts and results. The very letters of the alphabet are conventionalized pictures of things. Mind is incarnate and concentrate seeing. The visual centres of the brain are in the closest and most vital connection with all other brain centres. How easily, therefore, must a disturbance of the peripheral mechanism send a jarring and discordant thrill throughout the entire motor, sensory, and psychic

being. At once the microcosm is aroused to correction and adjustment; subordinate and commissurally connected centres feel the challenge and the overflow according to the accidents of weakness, diathesis, disease, and their varying powers of resistance. The result of this overflow, or switching, is a reflex neurosis, and from the supreme importance of the function of vision and the unusual strain that civilization puts it to, the eye becomes the greatest originator of these disturbances.

ORIGINAL ARTICLES.

ON HYPEROSTOSIS OF THE PRÆMAXILLARY PORTION OF THE NASAL SEPTUM, AND A DESCRIPTION OF AN OPERATION FOR ITS RELIEF.

By HARRISON ALLEN, M.D.,
of Philadelphia.

In a well-defined group of cases there exists at the lower part of the septum, anteriorly, between the triangular cartilage and the floor of the nose, a disposition to hyperostosis which may so far encroach upon the vestibule (as this passage is seen just within the plane of the nostril) as to create an obstruction. The triangular cartilage itself, in these cases, though it may remain straight, is usually deflected to the side occupied by the main portion of the hyperostosis. Fully one-third or one-half of this osseous growth lies below the plane of the nostril, and the obstruction which it causes is not removed by any of the means for correcting deviation of the septum. The existence of the hyperostosis can be demonstrated by passing a curved probe within the nasal chamber, placing its free end on the floor, and drawing the instrument forward. The probe is felt to touch a resisting mass at a distance, on an average, of one-half inch from the anterior edge of the nasal aperture. It is evident from such a conformation that the mucus which trickles to the floor of the nose cannot be easily removed, and that when inspissated it will excite irritation, and lead to insufficiency of nasal respiration.

Careful dissection shows that the growths can be best exposed by separating the upper lip from the jaw at the region of the nasal spine. The lip being elevated, an incision is made through the frænum, and a chisel is employed to break down the resisting mass of bone at the præmaxillary portion of the septum. In some cases a metacarpal saw is preferred, or a gouge can be used with advantage. A hand-drill is sometimes very effective. The single object in view is to remove as much bone as may obstruct the chambers. The bone is of great hardness, and rapidly dulls the sharpest instrument. It thus becomes necessary to have a number of freshly sharpened instruments for each operation. After the parts have been sufficiently reduced the triangular cartilage, if it be deflected, may be separated from the lower border of the notch, and set in a favorable position by the use of either pins or plugs.

It is hardly necessary to state that many phases of distress are relieved by less interference than is described above; but it is nevertheless true, that some patients who have had all the resources at my disposal exhausted without obtaining relief, were promptly cured, or greatly improved, by the supra-labial operation. I have operated many times, and in no instance have I observed any rise of temperature. I believe the procedure to be free from risk. The after-treatment is exceedingly simple. The lip being allowed to fall into position makes perfect adaptation, and closes the oral wound. Until the septum is attached in its new position, ivory or cotton plugs are used as splints. These must be removed daily for a week, at the end of which time the parts are entirely healed. The lip remains slightly swollen for a very short time, but I have never seen any inflammation.

Case I. *An inveterate, chronic, nasal catarrh greatly relieved by the supra-labial operation, after all other means had failed.*—W. J., twenty-eight years old, reported to me for catarrhal difficulties, arising from obstruction to the nasal respiration, of four years duration. I found hypertrophy of the right turbinated bone, and a sharp spur on the nasal septum at the junction of the anterior part of the vomer and the perpendicular plate of the ethmoid bone; the septum was deviated to the left. The anterior end of the left middle turbinated bone was the seat of a chronic hyperplasia. The quantity of discharge in this case was exceptional. It was constantly flowing, both day and night. The largest part passed backward, and greatly interfered with sleep and appetite. Its presence did not excite any reflex symptoms.

In January, 1885, under ether, I loosened the triangular cartilage from its inferior attachment, at the same time removing the hyperplastic membrane from the left middle turbinated bone, and the hypertrophied tissues from the right turbinated bone. The spur which was formed at the junction of the vomer and the perpendicular plate of the ethmoid was ablated with a saw, as originally recommended by me. Great relief followed this manipulation, but the triangular cartilage, in time, resumed its old position. In September, 1888, he reported a second time. Since, in this long interval, much of the original distress remained unrelieved, he had been under the care of leading laryngologists, and all had been done for him that was possible to do. Examination revealed no cause for interference with either the turbinals or the septum. I detected, however, that the præmaxillary portion of the septum was unusually thick, and, with the object in view of reducing its size, I proposed to him the supra-labial operation, which, up to that time, I never performed.

On December 1, 1888, I performed the operation under ether. Separating the under lip from the jaw, at the junction of the labio-alveolar mucous membrane, the nasal spine was exposed and freed from periosteum. A stout chisel was then used, which measured about two-thirds of an inch on its cutting surface. The instrument was pushed firmly against the junction of the spine with the triangular cartilage, thus separating the cartilage from the maxillary portion of the septum, and was thence directed downward and inward. It soon met with the hyperostosis, and could not be urged forward without the aid of a mallet. The chisel, being slightly wedge-shaped, increased the interval between the septum at the place of division and the floor of the nose, so that some relief of the strain under which the part had before suffered was to be expected. The sides of the mass were reduced by the saw.

The patient was greatly relieved by the operation, although not to the extent that I desired. There is still a disposition for the triangular cartilage to return to its old position, which, however, is, in great measure, under control.

Case II. *Chronic nasal catarrh, pharyngitis, deafness, vertigo, and impairment of memory; relief by intra-nasal treatment; a return of the pharyngitis in an obstinate form cured by the supra-labial operation.*—S. S. D., aged forty-nine; reported May 14, 1887. The patient had received a severe injury on the left side of the face when a boy. Nothing appeared to have followed the direct effect of this injury until the patient was thirty-seven years old. At this time he suffered from attacks of "sore-throat," and conditions connected with ineffective nasal respiration. In time nocturnal mouth-breathing was established; a headache of high grade was developed on the right side of the brow; the memory became impaired; the patient became dyspeptic, and was greatly annoyed with vertigo. The distress arising from these symptoms gradually increased until, at the time he reported for treatment, he was contemplating, on account of his ill health, retirement from business. Chronic aural catarrh supervened in 1884. The hearing distance on the right side was seven inches, and that on left side four inches. The vibrations of the tuning-fork were referred to the left side. The handle of the malleus was retracted on each side.

The nasal septum was so far deflected to the right, directly within the nostril, as to prevent any view being obtained of the interior of this chamber. On the left side the parts were open anteriorly; but, at the junction of the middle and anterior third, the septum was thickened, and hyperostosed in the præmaxillary portion, and greatly deflected to the right at the line corresponding to the juncture of the vomer and perpendicular plate of the ethmoid bone. The inferior meatus at the upper part was thus completely obliterated. Posterior rhinoscopy showed the septum to be uniformly thickened. The left choana was markedly smaller than the right in all its proportions. Lateral swellings on the vomer were conspicuous, the swelling of the left side being much the larger, nearly obliterating the choana. The left middle turbinated bone was nearly vertical; the turbinals were nowhere enlarged. The walls of the oropharynx were infiltrated, of a red color, and the entire region was excessively irritable. Quantities of tenacious mucus were seen occupying the pyriform sinuses.

On May 16, 1888, I advised that the patient be etherized, and the nasal chamber explored, the object being to determine its condition on the right side, and to remove the septal ledge on the left. The little finger being passed into the right nasal passage, I found to my surprise that the triangular cartilage readily yielded to gentle pressure, and permitted the finger to pass well into the chamber. The inferior turbinated bone was atrophic. A moderate amount of hyperplasia was detected at the anterior part of the middle turbinal. The only surgical measure at this time resorted to was the removal of the septal ledge on the left side, which was easily accomplished with a saw.

The patient returned to his home a week after the operation, and was not seen until November 5, 1888, when he presented himself with the following report. The pain over the right brow and the vertiginous symptoms had disappeared; digestion and the habit of mouth-breathing were improved; the hearing distance on the right side had increased to eleven inches, and that on the left side to seven inches; the tuning-fork was referred to the vertex; the memory was not improved.

The patient reported again in a fortnight, complaining that the pain had returned, the other symptoms remaining the same. I did not see him again until March 7, 1889, when the improvement recorded under note of November 5, 1888, was found unchanged. He had greatly increased in weight—before the operation he weighed 185 pounds, and at this date 224 pounds. The only symptom of which he complained was a slight discharge into the naso-pharynx, which annoyed him in the early morning. He remained in this condition until May 3, 1889, when he reported with the statement that the throat had remained perfectly comfortable for a year, then gradually became uncomfortable, and, at the date of report was about the same as before the operation. The headache, vertigo, and oral breathing had not returned; the hearing distance remained the same. A slight degree of fetor was noticed on the breath. I again advised another examination under ether, with the object of placing the triangular cartilage in a better position, and diminishing the thickness of the septum at the præmaxillæ.

Accordingly, on June 21, 1889, I performed the supra-labial operation. There was more oozing of blood than usual, and reflex neuralgic pains followed. The patient, however, made an entirely good recovery, and reported on October 8, 1889, with entire relief of all his symptoms, save the impairment of hearing and of memory.

November 13, 1889, the patient reported with a slight recent catarrhal pharyngitis, which excited anxiety. There was no return of the nasal difficulties. The hearing distance on the right side remained at eleven inches, but on the left side it had improved, the distance being eight inches.

Remarks.—This case is of interest on account of the acquired habit of mouth-breathing in an adult exciting chronic pharyngitis and aural catarrh. These symptoms were either greatly relieved or entirely removed by operative procedures within the nasal chambers. It is also interesting to observe that while considerable comfort was derived from the reduction of the septal spurs, which were placed far back within the nasal passages, entire relief from the nasal and pharyngeal symptoms was not acknowledged until the hyperostosis of the præmaxillary portion of the septum was removed.

Case III.—A. H. D., a lawyer, thirty-seven years of age, was sent to me by Dr. Lewis Taylor, of Wilkesbarre, Pa., October 4, 1888. The patient complained that from his seventh year he had suffered from nasal catarrh associated with attacks of spasmodic asthma. He was peculiarly susceptible to the odors arising from horses. These odors increased the secretions, including those of the lachrymal apparatus. The odors of the seashore had a similar effect, but were less constant and not so severe. Independent of these serious distresses, the catarrhal attacks were irregular, and were often dependent upon systemic causes as well as those of climate. Aggravated forms of the attacks were sufficiently common to interrupt seriously his professional engagements. A physician had, a short time previously, amputated the uvula, but without effecting relief. In 1880 symptoms of lachrymal obstruction appeared.

Examination showed that the nasal chambers were normal in all respects, except the præmaxillary portion, where the septum was enormously thickened anteriorly, and the floor of the left side elevated considerably above the level of the right. Both chambers were large anteriorly, just above the plane of the nostril. The pharynx presented the ordinary signs of chronic inflammation. Both lachrymal punctæ were small. I recommended that the supra-labial operation be performed. This was accordingly done October 18, 1888. The patient made a prompt recovery, and was immediately relieved of all his symptoms, excepting those which pertained to the lachrymal ducts. I last heard from this patient June 18, 1889. He remained perfectly free from all his catarrhal and asthmatical symptoms, and had been much improved by treatment, at his home, of the lachrymal obstructions.

Remarks.—This case is an illustration of the long-standing effects which can arise from irritations excited by the hyperostosis of the anterior part of the septum, and of the necessity of a surgical operation.

Case IV.—F. G., a machinist, aged twenty-four years, was sent to me by Dr. C. A. Wirgman. Since childhood he had suffered from nasal obstruction and catarrh. The anterior portion of the nasal chamber was obstructed by thickenings of the nasal septum over the præmaxillæ.

On June 3, 1889, I performed the supra-labial operation. The parts were exceptionally dense; the nasal spine was long, with a broad base; the triangular cartilage was bent far over to the right, completely occluding the nasal chamber at this point. To remove this occlusion the cartilage was separated from the vomer and anterior nasal spine by means of my septum knife. It was then pushed over toward the left side and was held in position by cotton pledgets. I did not see the patient again for a week, as he was placed under the care of Dr. Wirgman. He had returned to his work—that of a laborer in an iron mill—the third day after operation. He was instantly and entirely relieved from all his distress, which has not since returned.

Case V.—D. S. W., twenty-four years of age, reported, June 10, 1887, at the recommendation of Dr. C. H. Spooner, suffering from attacks of epistaxis. The disposition to hæmorrhage was hereditary, being transmitted by the father. The subject's brothers and sisters possessed the same peculiarity. One sister died of consumption, and he said that all his family had weak lungs. Attacks of bleeding occurred about every month or two. The patient complained of sensations of heat and dryness within the nostrils, and he was constantly disposed to pick the right nostril, and to wake up in the morning from unrefreshing sleep to find the mouth and throat parched. Nasal respiration was normal except at night, when oral breathing was established. He was treated in early life for attacks of stomatitis by Dr. Spooner, who believed the patient to be strumous.

Inspection of the nasal chambers showed great thickening of the præmaxillary portion of the septum. The deflection of the triangular cartilage to the right was sufficient to effect contact with the anterior end of the inferior turbinal. In almost its entire extent the cartilage was the seat of a superficial ulceration which bled upon the slightest touch. A peculiar odor was detected about the parts which I have noticed with the subjects of chronic bleeding. It is apparently caused by the decomposition of mucus containing blood-clot.

The left choana was very much smaller than the right and possessed a nearly vertical middle turbinated bone. I treated the ulcerated surface with applications of nitrate of silver, but without success. I saw the patient every week or fortnight until October of the same year, when he was attacked with an acute coryza followed by pharyngitis and a great deal of œdema. This attack greatly increased the difficulties attending nasal respiration. On the sixth day a spontaneous hæmorrhage occurred which appeared to be from both nostrils. I saw him at noon of the same day of the attack, and plugged the nostrils. The hæmorrhage was arrested for seven hours, but returned at eight o'clock in the evening of the same day, when the parts were again plugged, this time permanently stopping the bleeding.

The inferior turbinals were subject to great alterations in size, but, as a whole, they were normally proportionate, the left being slightly larger than the right. The masses in the naso-pharynx were seen to vary in size at different times, and occasionally to project from the choana into the naso-pharynx, but without exciting, at such times, any distress.

Believing that the unrelieved ulceration was a constant exciting cause of hæmorrhage, and the condition of mouth-breathing a predisposing cause to laryngeal or pulmonary phthisis, I operated on him, February 19th, to relieve the strain of the triangular cartilage, trusting by this manipulation to cure the ulcerated surface. The patient did well until June 25th, when a profuse bleeding occurred. This was controlled by pressure from without, proving that the bleeding-point was near the nostril. A week later a second bleeding occurred, which was promptly checked by the patient pressing the alæ of the nostril firmly against the septum. He made a good recovery.

Six months after the operation he reported, saying that all the symptoms had disappeared, and that he had had no bleeding since the attacks immediately after the operation. The alæ was entirely healed.

Remarks.—In this case an intractable ulcer of the triangular cartilage, in an hereditary bleeder with a strumous history, was cured by relieving the nasal septum from strain at its anterior part. Owing to the constitutional peculiarities the operation was essayed under difficulties, but none of these interfered with a good recovery and correction of an annoying and dangerously diseased condition.

The operation of resetting the triangular cartilage, as performed by myself, consists in separating the lower border of the cartilage from the triangular notch, pushing it toward the larger cavity of the nose, and fixing it in its new position. Should the spur on the smaller side be very prominent, it may be sawed off. In the absence of hyperostosis of the præmaxillary portion of the septum, this little procedure is often all that is required to give comfort. In all operations on the septum it must be remembered that no radical increase of diameters is to be sought for. A tendency for the parts to return to their original positions is in constant operation. The surgeon must not be disappointed to find the triangular cartilage disposed to return to its primal place; but while the parts often look as though little had been accomplished, the reports of the patient are encouraging. Something in the way of relief has been accomplished and in the great majority of cases sufficient to warrant acceptance of the procedure as a safe means of curing the symptoms attending nasal obstruction. Occasionally, after healing is completed, small fibroid or cartilaginous nodules are seen occupying the inferior meatus. These result from the process of cicatrization, and they must be removed by the knife or the scissors.

Simple Method of Curing Obesity.—A French journal announces a cure for obesity which is as simple as it is said to be effective (*Weekly Medical Review*). The method consists in never eating more than one variety of food at a meal, without any restriction in the amount taken. Two cases are reported illustrating the effects of the treatment.

MITRAL STENOSIS IN CHILDHOOD.[1]

By WILLIAM A. EDWARDS, M.D.,
of San Diego, Cal.
Fellow of the College of Physicians of Philadelphia, and of the American Pædiatric and Philadelphia Pathological Societies; formerly Instructor in Clinical Medicine in the University of Pennsylvania; Physician to St. Joseph's Hospital; and Associate Pathologist to the Philadelphia Hospital, etc.

The constant advance in medical knowledge is in no way better illustrated than by the fact that the mitral stenotic murmur is again tossed into the arena of controversy, and that the object of this paper is partly to defend its existence.

First referred to by Gendrin in 1841, and differentiated by Fauvel in 1843, it had a somewhat checkered career until 1862, when Gairdner so ably described its characteristics that its position in the nomenclature of cardiac disorders seemed to be assured. Very recently, however, the old dispute, opened by Barclay, has been renewed by Dickinson (1887), who does not accept the statement that the presystolic murmur is indicative of mitral stenosis; but Balfour, Gairdner, Bristow, and more recently Sansom, have most vigorously re-asserted the diagnostic importance of this murmur. It is the object of the writer of this paper to add his testimony to the value of this sound in interpreting conditions of obstruction at the mitral orifice. It is my opinion that obstruction at the left auriculo-ventricular orifice presents a most characteristic sound.

Having stated the position we occupy in regard to this controversy, we will proceed to a consideration of the murmur *seriatim*. By mitral stenosis we understand an alteration in the histological structure of the left auriculo-ventricular orifice which causes an obstruction to the passage of the blood from auricle to ventricle.

The accompanying Table (p. 187) presents a series of cases of mitral stenosis taken from my case-book.

Etiology.—This condition is probably never congenital, although some observers have stated the contrary. The most recent and most authoritative communication upon the subject, that of Osler in Keating's *Cyclopædia*, dwells upon the condition of tricuspid stenosis with atresia of the orifice, but does not make any reference to a similar condition on the left side, although illustrations are appended of an irregular differentiation of the segments and of numerical anomalies of the curtains of the valve. Furthermore, it is not at all likely that fœtal endocarditis would produce this condition, for endocarditis in the fœtus is, almost without exception, confined to the right side: and again, the murmur has perhaps never been recorded during the very early years of life. In

[1] Read before the Medical Society of the State of California, April 16, 1890.

No.	Age.	Sex.	Murmur.	Concomitant disease.	Results and remarks.
1	Observed from 8 to 12 years.	Male.	First, presystolic; later, regurgitant; thrill. Early reduplication of second sound disappeared later.	Rheumatism and anæmia.	Child under careful observation for four years. Dilated hypertrophy for last two years. Œdema, dyspnœa, and death from exhaustion. Autopsy: Buttonhole mitral. A photograph of the boy in his eighth year is pictured in Bruen's Physical Diagnosis. He died under my observation in the Hospital of the University of Pennsylvania.
2	12 years.	Female.	Loud, rasping, presystolic murmur, followed by low purring, systolic bruit; thrill.	None; she and her friends can recollect no attack of acute disease, and state that the child has hardly been sick a day in her life. Sought advice for shortness of breath.	Case is fully reported in Diseases of the Heart and Circulation in Infancy and Adolesence, by Keating and Edwards, 1888, p. 110. Alive at report.
3	13 years.	Female.	Pronounced presystolic, with low systolic.	Coxalgia; enuresis; some hypertrophy; heart acting well.	Observed in consultation with H. W. Yeamans, M.D., San Diego. Alive and well at report.
4	7 years.	Female.	Presystolic; thrill.	Anæmia and deficient personal hygiene.	Observed in Children's Hospital, Philadelphia, with C. W. Kollock, M.D.
5	9 years.	Male.	Pronounced presystolic; apparent reduplication of second sound.	Ill-defined rheumatism, not articular.	Private practice, Philadelphia. Alive at report.
6	12 years.	Male.	Presystolic.	Ill-nourished. Died during a severe epidemic of measles. Heart was hypertrophied, but auricle dilated.	Death. Stenosis marked, orifice irregular, and valve segments fibroid; funnel-shaped. Private practice, Philadelphia.
7	7 years.	Male.	Presystolic, with slight systolic thrill.	Bulging præcordium; emaciated; pale; anæmic; no rheumatism; hemiplegia and aphasia.	Death. Post-mortem: Buttonhole mitral; stenosis marked; clots fibrinous and organized; anterior and middle cerebral arteries of left side contained emboli. Observed in Third Outdoor District, Philadelphia.
8	11 years.	Female.	Typically presystolic; thrill.	Bulging præcordium; top-heavy appearance, due to auricular dilatation. No rheumatism. Aphasia; hemiplegia.	Death. Post-mortem: Funnel-shaped mitral; clots fibrinous; middle and anterior cerebral plugged. Observed in the Third Out-door District, Philadelphia.
9	6½ years.	Female.	Presystolic.	Anæmia; ill-nourished and poorly developed; slight rheumatism; frequent attacks of diarrhœa.	Alive at report. Heart-beats irregular; apparent reduplication of second sound. Private practice, Philadelphia.
10	9 years.	Male,	Predominant, loud presystolic, with low systolic thrill.	No symptoms; sought advice on account of nightmare.	Alive at report. Private practice, Philadelphia.
11	12 years.	Female.	Loud presystolic thrill.	No rheumatism; few symptoms; short breath most exacting.	Alive at report. Private practice, Philadelphia.
12	5½ years.	Male.	Presystolic.	Ill-defined rheumatism; dyspnœa; præcordial bulging; anæmia.	Died from asthenia. Auricle dilated; contained clots; ventricle dilated; hypertrophy. Observed in the Third Outdoor District, Philadelphia.

most instances the child has reached or passed its fifth year, although occasionally cases are recorded at a younger age, as, for example, Chapin's[1] case of two years, and Sansom's[2] case of four years and three months. The latter observer has also recorded the case of a baby two months old who presented a ring of granulations of endocarditis with thickening of the mitral valve; so that, on the whole, we can conclude that the congenital origin of mitral stenosis is not proven. Not so in regard to rheumatism; the association between the two conditions is, as we all know, as definite as that which exists between regurgitation at the same valve and the rheumatic diathesis. An analysis of the recent literature shows that the association is apt to be with a rheumatic condition that is not marked or acute, but latent and insidious, in contradistinction to the severity of the attack in which the regurgitant murmur is usually produced. For example: in Chapin's series of 31 cases, 20 presented rheumatic involvement, as follows: In 6 there was a history of rheumatism in the immediate family, but none in the patient; in 4 cases there was rheumatism in the family, and the child had also been rheumatic. In 10 instances the patient alone presented a rheumatic history. Sansom most aptly remarks that the stenosis is rarely associated with

[1] New York Medical Record, January 4, 1890, p. 5.

[2] American Journal of the Medical Sciences, March, 1890, p. 284.

the explosive varieties of rheumatism. Of his 40 cases, 26, or sixty-five per cent., were rheumatic. Cheadle has noted an even more intimate association—that is, seventy-nine per cent., or 44 cases out of 57, being rheumatic. This, as we see, leaves a small proportion of cases which occur independently of any rheumatic taint, cases whose etiology has been the cause of much speculation, and not infrequently of the advancement of somewhat improbable hypotheses in endeavoring to unravel the problem. Sansom, indeed, loath to relinquish the rheumatic taint as a causative factor, states that even in cases in which there was no history of rheumatism obtainable the changes in the endocardium were identical with those that occur in association with the d athesis; in fact, he was unable to differentiate these cases from those that were known to be rheumatic; and Chapin, in an earlier paper (1886), presented notes of 26 cases of heart-disease in rheumatic children, in which only 4 presented evidences of mitral obstruction, and in 3 instances it was associated with other murmurs. Of the remaining moiety of cases, the etiology has been placed in one or other of the accepted causative agents of valvular derangement.

Duroziez, Landouzy, and Schnell[1] testify to the possibility of a *so-called* idiopathic origin of mitral stenosis, more particularly in women and children, an illustration of which would seem to be a case recorded by Sansom,[2] in which there were signs of wasting and long-continued malnutrition. The girl, aged nine, whose general appearance and condition suggested tuberculosis, wasted rapidly and had night-sweats. The physical signs, however, were "a typical presystolic murmur, with sharp, loud impulse, and the signs of considerable cardiac hypertrophy."

Another series of cases seem to arrange themselves naturally under a derangement of the nervous system. One of Chapin's cases had chorea but not rheumatism, and nine of Sansom's cases manifested chorea, two were right and two were left hemichorea; in several of his cases hemiplegia, paresis, and epilepsy were associated with the vascular lesion. Then, again, a mitral stenotic murmur may be heard in association with other valvular murmurs; particularly is this the case when the aortic leaflets are incompetent, allowing regurgitation at this orifice, with a constant damming back of blood in the ventricle, which perhaps might float the mitral curtains out into the current, and thus produce an obstruction in the direct mitral current—a mechanism by which Guitéras has endeavored to explain the cases of what he terms direct functional murmur. A small number of cases are no doubt due to the fact that a valve which was primarily incompetent and which permitted regurgitation, may undergo further change, and become stiffened, indurated, and stenosed, thus giving rise to the murmur of stenosis.

Diagnosis.—The peculiar percussion outline in this affection was well illustrated by two cases, one of which was under my observation for about four years in Philadelphia. The heart was secured at autopsy in the Hospital of the University of Pennsylvania. The other case I have fully reported elsewhere.[1] The increase in the size of the auricle gives the heart a top-heavy appearance, and in the first case an auricular impulse was many times demonstrated to the class. This pulsation, seen in the second and third left interspaces, always preceded the apical impulse, and, to our mind, clearly demonstrated the presystolic impulse of an hypertrophied auricle dependent upon mitral stenosis, and, in consequence, the presystolic time of the murmur. It is granted, of course, that an auricular impulse is not a constant concomitant of mitral constriction (in Sansom's series it was present in 4 of 35 cases); but, when it does exist, its significance is evident. Not so, however, with a thrill, which is a much more constant attendant, and was present in 7 of our cases and absent in 5. This thrill was always presystolic—that is to say, it ceased abruptly with the occurrence of the apex beat; it was usually felt best by the tips of the fingers placed somewhat above and to the right of the apex. The thrill may not be constant in a given case; it may exist at one examination, and be absent at the next.

It is more particularly, however, to the murmur that we desire to call attention. A murmur heard above and within the apex; that ceases abruptly with systole, immediately upon the apex striking the chest-wall, or, with the finger upon the carotid, as soon as the pulse is felt; a murmur which in a child is usually harsh or rolling in timbre, and may commence immediately after the second sound and occupy the entire long pause, or may be audible only at the termination of this pause (the presystolic period or according to some the post-diastolic) is, as we understand it, diagnostic of mitral stenosis.

But to assist us in our diagnosis there are certain concomitant signs, such as accentuation of the pulmonary-artery second sound, and seeming reduplication of the second sound, explained by some by the fact that the unfilled right chambers cause a right ventricle and pulmonary artery systole to precede the same act upon the left side, as Da Costa remarks in illustration of the fact that practically two hearts exist in the chest. Sansom, however, considers this an example of what has been recorded by Henry

[1] Annual of the Universal Medical Sciences, 1888.

[2] American Journal of the Medical Sciences, March, 1890, p. 234.

[1] Diseases of the Heart and Circulation in Infancy and Adolescence. Keating and Edwards, 1888.

as a case of asynchronous contraction of the cardiac ventricles.[1] Reduplication may be due to a sudden tension of the mitral valves following the normal second sound and preceding the presystolic murmur. We have already called attention to the thrill, which may be associated with the murmur, or may exist independently. It must be borne in mind that the presystolic murmur of mitral stenosis is not constant, it may be present one day and absent the next. The largest proportion of cases is accompanied by the murmur of regurgitation, but in 7 out of the 12 above cases the murmur of stenosis alone existed. In differentiating it is well to remember, with the other differential signs, that systolic murmurs fade away, whereas a presystolic murmur ends abruptly with systole.

Reference must be made to the careful work of Dickinson,[2] although we are unable to accept his deductions. He concludes that the murmur we are considering usually runs into the systole about as far as the carotid beat and then ends with the terminal knock. He, however, concedes the little murmur which follows the second sound and occurs in the mid-diastolic period to be the true murmur of mitral stenosis; this he terms the old direct mitral murmur, made from auricle to ventricle through a much-contracted valve. It is, however, not granted by this observer that the murmur which begins after this has ceased (the presystolic murmur of this paper) is correctly termed presystolic. He prefers to consider it really a regurgitation, or a direct mitral murmur which rumbles up to near the end of the ventricular systole. This effort of Dickinson to prove the systolic nature of the murmur that we are pleased to call presystolic, concludes in this wise—"Does the lifting of the chest-wall, as felt with the fingers, indicate the systole? Does the murmur accompany the lifting? Does the carotid beat follow the murmur without an interval? If these do so, the murmur is systolic." We, of course, concede that the chest-lifting indicates the systole, but do not believe that the murmur accompanies this lifting, nor can we reconcile our answer in the affirmative in regard to the last proposition. Indeed, it would be still harder to concede these propositions after a careful study of Fenwick and Overend's paper.[3] The cardiograms of these observers demonstrate beyond peradventure that the murmur commences immediately before the ventricular contraction, and that the bruit is both presystolic as regards sound and contraction. Gairdner has suggested, and we are heartily in accord with him, that the auricular systole gives to the blood column an additional impetus, thus increasing its rate of flow through the constricted valve, causing the fluid to vibrate and the sound thus produced becoming audible to us as the presystolic murmur.

We quote two conclusions from the above observer, the application of which will be obvious to all.

"1st. The auriculo-ventricular valves occupy a horizontal position during the systole of the ventricle, while the papillary muscles contract simultaneously with the rest of the ventricular wall. The ventricle does not empty itself completely, there being a certain amount of residual blood.

"2d. The mid-diastolic mitral murmur in mitral stenosis owes its existence to the influence of the high pulmonary tension. The latter also plays an indirect part in the production of the early and late (presystolic) mitral murmur; but the immediate exciting cause of the early diastolic is the negative pressure of the left ventricle, while the late diastolic is usually due to the force of the auricular contraction. The murmur and the thrill coincide with each other in the cases we have examined."

The affirmative view of the diagnostic significance of presystolic murmur in mitral stenosis has been most ably defended by Reynolds,[1] but space forbids further reference to it. One has but to read the little work of Davies[2] on the mechanism of the circulation of the blood through organically diseased hearts, to be further convinced of the fallacies of the statement of those who consider that the murmur indicative of mitral stenosis is systolic in rhythm.

Clinical Symptoms.—As a rule, these resemble somewhat closely those of regurgitation at the same valve. There are dyspnœa, cough, and later, general or local dropsy, delirium cordis and tachycardia, or cardiac distress. Some of our cases, as we have already stated, have been very insidious in their onset; indeed the first physical signs were, apparent reduplication of the second sound followed in a variable time by the typical presystolic murmur; in other children who had presented a systolic murmur, a presystolic murmur would be found at a subsequent examination, either replacing the former or appearing as a concomitant. Other cases, which, however, are in the minority, may present evidences of lesions in the nervous system as the most evident symptoms of mitral stenosis. But two of our cases presented such an association; that is, hemiplegia and aphasia in connection with a buttonhole mitral; though Sansom in thirty-eight cases has observed quite a number with manifestations of nervous disorders, such as chorea, epilepsy, hemiplegia, and localized palsies from emboli. As this observer remarks, it is a fact worth noting that, with the exception of chorea, not one of these severe lesions of the nervous system

occurred in children who presented mitral insufficiency.

Prognosis.—In the child, unlike the adult, we do not fear the absence of compensatory hypertrophy, but rather do we fear the known liability to recurrences of rheumatic endo-pericarditis; and superadded to this danger is the ever-present liability to embolism.

As we have stated elsewhere the inherent power of the growing heart is usually sufficient to allow the organ to accommodate itself to the organic alteration, and, in the absence of new invasions of the disease, to permit the child to attain maturity with a fair degree of health. On the whole, however, in early life, mitral stenosis probably more often proves fatal than does regurgitation at this orifice.

PERFORATING ULCER OF THE STOMACH, WITH THE REPORT OF A CASE.[1]

By U. O. B. WINGATE, M.D.,
of Milwaukee, Wis.

That the early diagnosis of ulcer of the stomach, which may perforate the gastric walls and end the life of the victim, is often beset with the utmost difficulty, I believe cannot be gainsaid. With the object of calling attention to this difficulty, I venture to report the following case and to make some observations:

B. G., female, five and a half years of age, gave the history of a weak stomach from birth. Has passed through a severe attack of membranous croup and several gastro-intestinal attacks of varying severity. During the past summer has been quite well—occasionally, however, complaining of some pain in the stomach, and has had diarrhœa at times, but which was not sufficiently severe to require medical treatment—so thought the parents.

On Friday, October 12th, she came home at noon, after having been playing with other children, complaining of feeling ill, and soon vomited freely. Of what this ejecta consisted I was unable to learn definitely, but the mother was quite sure that it contained nothing remarkable or unusual. She could not find that the child had eaten any unusual food while out; at home her diet was always carefully regulated. She passed a restless night and was no better in the morning. In the afternoon of this day, Saturday, when I saw her for the first time, she appeared very ill. Pulse 140; temperature 102° F.; tongue furred with quite a heavy yellowish-white coating; stomach tender on pressure; bowels constipated; abdominal walls retracted and muscles rather rigid. No cardiac or pulmonary symptoms. The next day, Sunday, she was no better, and was still inclined to vomit everything swallowed. I saw her twice this day, and after several enemata given by the mother, an evacuation of the bowels was obtained, but nothing unnatural was observed in the matter evacuated. After this she seemed better, passed a good night, and on the next morning, Monday, her pulse was 120 and temperature 99° F. She still vomited occasionally, and was quite irritable, but the latter symptom was not unusual to her. On Tuesday and Wednesday nothing was noted and she appeared to be improving. On Thursday morning at my visit her pulse was 115; temperature normal; she was retaining lime-water and milk, and a little wine whey. She wanted to get up, but this I advised against, though I fear my advice was not heeded. That evening the father called at my office, and stated that the child's hands were cold, but that she seemed bright and strong, and he did not think it necessary for me to see her. I asked him to call me on his return if she appeared worse. I heard nothing until early the next morning, when I was telephoned for, and responded at once, to find the patient in complete collapse; pulseless; feet and hands cold and purple; eyes sunken; mind clear; stomach and abdomen tympanitic; stomach somewhat prominent. The liver dulness could not be made out. There was paroxysmal pain, and at times regurgitation of thin, greenish fluid. The parents, when told that the child was past hope could not believe me, and called in another physician who resided near, and who in my presence concurred in my diagnosis and statements. The patient died in a few hours.

An autopsy could not be obtained; however, I do not think there can be any doubt about the diagnosis.

Up to the time of the collapse I had considered the case one of mild gastritis, and though the idea of an ulcer was present, it did not make much impression on my mind. I now believe that an ulcer had existed for a long time and that the gastritis hastened the perforation.

There are some points of interest connected with this class of cases to which I desire to refer briefly. Brinton was able to collect two hundred and thirty-four cases of perforation from ulcer of the stomach, and, of course, many cases are not reported. The largest number of perforations occur between the ages of fourteen and thirty years. The ulcers which perforate are found about twice as frequently in females as in males—corresponding about to the ratio of ulcers generally in the sexes.

The location is important, from a surgical point of view, as well as interesting. Thus, according to Dreschfeld's report, 85 per cent. of ulcers situated on the anterior wall of the stomach, 2 per cent. of those on the posterior wall, and about 10 per cent. of those located at the pylorus, perforate. The history is also interesting and important. In many cases where perforation takes place the symptoms of gastric ulcer are wanting. Profuse hæmatemesis, excessive and constant pain, and symptoms of dila-

[1] Read before the Milwaukee Clinical Society, May 13, 1890.

tation of the stomach are, as a rule, absent. This is accounted for by the location.

Sudden pain, often of a paroxysmal character, is said to be almost always present. Sudden collapse is present if the perforation be at all extensive. Epstein has called attention to an important symptom, viz., rigidity of the abdominal muscles, or walls of the abdomen. This is present whether the walls are retracted or distended, is probably due to irritation of the peripheral nerves, and gradually subsides with the progress of the case. Tympanites is always present—in some cases the region of the stomach will bulge, while the abdomen is retracted. An important diagnostic point in connection with tympanites is the absence of liver dulness, due to the presence of air in the abdominal cavity. Vomiting is reported to be usually absent in cases of perforation. After perforation, death is almost invariably the result. Some cases of recovery are reported, but in them there is the possibility of an incorrect diagnosis.

The question of surgical interference is an important one. The difficulty of diagnosis immediately after perforation perhaps is an objection, but when seen early, even if in doubt, where collapse is advancing, and the pulse present, but increasing in frequency, I believe that abdominal section should be performed at once.

In the case which I report there was so little life left when seen after the perforation, that an operation was out of the question. Had I seen the patient the night before, when the father reported the cold extremities, perhaps something more could have been done.

204 Biddle Street.

CLINICAL MEMORANDA.

MEDICAL.

Case of Purpura Hæmorrhagica Rheumatica. (Peliosis Rheumatica: Morbus Maculosus Werlhofii.)[1]

Eddie D., aged thirteen years. Previous health good. His first attack was in March, 1889, and began with swelling of all the joints, pain, especially in the knees and ankles, a purpuric eruption over the entire body, and pain in the stomach and vomiting.

The pain in the knees and ankles was excruciating. He was put on a diet of milk and Mellin's food, and recovered in two weeks. This attack followed prolonged exposure and excitement at the base-ball grounds—the boy being infatuated with the game was frequently all day without food, except ginger cakes, pie, and peanuts, and sat on the rough benches of the ball grounds in cold winds, in rain, or in heat.

The second attack was in September, 1889, and was similar in character, except that the swelling and eruption were confined to the right half of the body. He had then been exposed to scarlatina.

The treatment up to this time had been acids, iron and quinine, and, to relieve pain, morphine.

The third attack was on November 15, 1889, and was similar to the preceding, but more severe. Pain in the abdomen and left side of chest was intense. In addition to the purpuric eruption there were hæmorrhages from the bowels and bladder, and, in large patches, into the skin. No hæmorrhage from the nose or lungs.

There had been very little fever during the attacks, the temperature seldom rising above 100°.

In the third attack he was delirious, and had dyspnœa, swelling of the forehead and conjunctivitis. Arsenic, which he had been taking for several weeks, was discontinued.

On December 17, 1889, and on February 27, 1890, he had relapses. After this to the present time relapses recurred at intervals of a month or six weeks, but were less severe.

During the intervals he is not perfectly well, though comparatively comfortable and free from pain. Since the beginning of the disease the purpuric eruption has never been absent.

The urine was examined from time to time, and, excepting the presence of blood, was found normal. On one occasion, however, there was a greatly diminished amount and much albumin, evidently due to acute nephritis.

Dr. Theobald Smith, Bacteriologist to the Government Agricultural Department, was kind enough to examine the blood, but discovered nothing abnormal, as will be seen by the accompanying report:

"*January 21, 1890.* The blood from the finger was dried on a cover-glass, and stained with alkaline methylene blue. Some of the preparations were decolorized in one-per-cent. acetic acid. There was no change in the size or form of the red corpuscles. Occasionally isolated corpuscles were observed, which retained the stain faintly. These forms are probably young corpuscles. The leucocytes were slightly increased in number; otherwise the blood elements appeared normal."

Dr. Smith also sent the following interesting note of a hæmorrhagic disease that occurs among guinea-pigs:

"Among guinea-pigs, kept for experimental purposes, a disease occasionally appears which usually ends fatally and may carry off the greater number of those living together. The disease seems to be due to the exclusive use of dry food, such as grain of various kinds. When the food is changed, and vegetables, fruits, etc., are given, the disease is checked and disappears. That it is a food disease I feel quite certain. The examination of the dead animals reveals, as a rule, extensive subcutaneous and intra-muscular ecchymoses, limited chiefly to the limbs. Occasionally they are found on or in the muscles of the chest and abdomen. The internal organs contain no bacteria."

The characteristic symptoms in this case of peliosis rheumatica are:

Swelling and pain in the large joints, closely resembling rheumatism, but coming and going sometimes within a few hours.

The characteristic ecchymoses of true purpura are

[1] Patient was presented to the Association of American Physicians, May 14, 1890.

present. There are hæmorrhages into the bladder and bowels, but none from the nose or lungs.

Of particular interest in this case was a peculiar hæmorrhage into the true skin—apparently between the epidermis and the true skin—which destroyed the skin by gangrene. The most marked of these ecchymoses were in the skin of the abdomen—two patches, each the size of the palm of the hand, one on the left, the other on the right of the navel. These ecchymoses appeared within half an hour, and were at the beginning perfectly black and painless patches of true gangrene. In a few days a line of demarcation formed, and in due time the dead tissue sloughed, leaving a granulating surface which healed slowly, forming scars which can still be seen.

The boy formerly had a tight phimosis, for which I intended circumcising him, but one of these sloughs appeared on the under surface of the prepuce and cured the phimosis.

Among the symptoms were frequent vomiting and violent pains in the abdomen.

The abdominal pain at times was so violent that I thought there was a peritonitis from a hæmorrhage into the peritoneum, but the absence of tenderness and the rapid disappearance of the pain rendered this view improbable.

The attacks, as stated, are remittent in character; exacerbations occurring at intervals of one or two months. The later attacks have been less prolonged than the earlier.

As to treatment, the medicine that appears to have done the most good is arsenic—and possibly salol given for relief of the rheumatic symptoms.

Washington, D. C.

MEDICAL PROGRESS.

Craniectomy.—The Paris correspondent of the *Lancet* (July 19, 1890) writes that at the last meeting of the Academy of Sciences Professor Verneuil called attention to an operation just performed by Professor Lannelongue on a nearly idiotic girl four years old, whose skull was about one-third the normal size. She could not walk or stand without support. M. Lannelongue attributes this condition—microcephaly—not only to the insufficient capacity of the skull but to cerebral lesions caused by pressure, and in the case of the child above referred to he believed that if more space were given to the brain the condition would disappear. Acting on this hypothesis, he made along the median line of the cranium an incision corresponding to the sagittal suture and extending from the frontal to the occipital suture. On the left of the incision he removed a piece of bone about three and a half inches long by half an inch wide and including the entire thickness of the skull. The dura was left intact and the superficial wound was united without drainage. Union took place by first intention. The operation was performed on May 9th, and on June 15th a change in the condition of the child was apparent; she walked, smiled, and had lost much of her previous apathy. M. Lannelongue has quite recently performed a similar though more extensive operation on another child.

Hypodermic Injections of Ether in the Treatment of Neuralgia.—The parenchymatous injection of ether for the relief of neuralgia is by no means a new method of treatment, though it has had but few advocates, and has been practised to only a limited extent. Kumps (*Revue de Thérapeutique*, June 15, 1890) again brings the method forward as a valuable addition to the therapeutics of neuralgia, and cites a number of cases in which relief followed the injection of equal parts of alcohol and ether into the neighborhood of the affected nerve. Among other cases reported by him are the following: A neuralgia of the shoulder which for two weeks had prevented sleep and had resisted a variety of other methods of treatment, was cured by a single injection. Two cases of sciatica, both of which were much relieved after the first injection. Two cases of facial neuralgia, and three of rheumatic neuralgia of the head were also relieved.

Kumps uses the injections not only in cases of true neuralgia but in rheumatic pains and in torticollis. Two cases of the latter disease were cured by the method, only one injection being required in each case. The amount of the mixture used by the author is 30 minims, and he states that though the pain of the injection is considerable it soon passes away. There is also often some local swelling which can be dissipated by gentle manipulation.—*London Medical Recorder*, July, 1890.

Keen's Methods of Compressing the Subclavian Artery.—All surgeons know the difficulty of maintaining steady and effectual occlusion of the subclavian artery by pressure above the clavicle where the third part of the vessel crosses the first rib, and will welcome the following simple plans devised by Professor Keen (*Annals of Surgery*, July, 1890):

A rolled bandage two inches wide is placed above the clavicle over the position of the artery, as ascertained by the finger. The strong rubber strap which accompanies Esmarch's bandage is then passed over the roller above the clavicle, then down the back, between the thighs, and up in front of the chest. The ends can then be held by an assistant, or, better, tied or hooked together. If it is desired to release the artery, the rubber strap is slipped off the bandage: pressure can be renewed as easily. An assistant should stand on the side of the patient opposite to the side of the operation, to steady the strap and bandage.

The advantages of this method are, that it is reliable, that the compression will be maintained, even though the patient should struggle, and that not only is the assistant not tired out, but he has one hand free for other purposes. An Esmarch bandage can, of course, be applied to the arm before compressing the artery.

With the elastic strap of the Esmarch apparatus, Professor Keen found some difficulty in retaining the roller in place over the artery. To obviate this, he has resorted to the elastic *bandage* of Esmarch, which is applied as follows: The tendency to displacement of the roller downward below the clavicle is counteracted by laying the free end of the elastic bandage on the chest, then passing the unrolled end over the shoulder and down the back. If the *strap* is used the natural tendency, when it is placed in position, is to pull on both ends at once, and the upper end being drawn downward tends to displace the roller in the same direction. If

the elastic *bandage* is used, traction being made with the unrolled part of the bandage, over the shoulder *from front to back*, this subclavian displacement is prevented. To prevent outward displacement, the alternate turns of the bandage should be carried under the opposite axilla. By these means the roller is held in place fixedly, and requires no care from an assistant.

The Faradic Current in Uterine Hæmorrhage.—DR. EUGENE BOËR writes (*Lancet*, July 19, 1890) that though iodoform-gauze tampons, if carefully applied, will usually arrest the flow in menorrhagia, still, cases occur in which this plan does not succeed, probably because the hæmorrhage is due to atony of the uterus. In one case of this kind, that of a girl of eighteen, having tried all the usual internal and local remedies, and the patient having become unconscious from loss of blood, he used the faradic current, which arrested the bleeding in ten minutes. When, three days later, there was a return of the hæmorrhage the method was again used with success. The effect was permanent, for, though the faradization had to be resorted to at the next period, the subsequent one was normal. A similar plan of treatment proved equally successful in the case of a multipara with profuse and intractable menorrhagia. Dr. Boér at first applies the negative electrode directly to the cervix, and, after the arrest of the hæmorrhage, to the perineum, the positive pole being applied with some little pressure to the abdominal wall over the fundus of the uterus.

An Enormous Nasal Polyp.—SCHMIEGELOW (*Medicinske Selskob i Kjobenhavn*) demonstrated, at a recent meeting of the Copenhagen Medical Society, a nasal mucous polyp which was five inches in length and extended through the entire right nasal cavity, prolongations reaching to the edge of the soft palate. The growth was removed with a wire loop, and its point of origin found on the posterior end of the lower turbinal.—*Annals of Surgery*, July, 1890.

Treatment of Chancres by Creolin.—In the *Bulletin Générale de Thérapeutique*, July 15, 1890, BUSQUE, of Brazil, writes a note to Dujardin-Beaumetz detailing his experiences in the treatment of chancres by this means.

His custom is to apply to the sore a solution of the strength of from 12 to 20 parts to 1000, and he believes that the progress of the malady is shortened and relief speedily obtained. Compared to iodoform Busque thinks these solutions of creolin equally serviceable. The best treatment, however, is to combine these drugs, using the creolin solution as a wash and then iodoform as a dressing.

Nephrectomy for Pyonephrosis.—WISHART (*Montreal Medical Journal*, July, 1890) reports two abdominal nephrectomies for hydronephrosis, and draws the following conclusions:

1. That in a large proportion of cases of advanced hydronephrosis, where the tumor fills the abdomen, it is impossible for the average operator to say whether the growth is a cyst of the kidney or an ovarian tumor.

2. That supposing hydronephrosis is suspected, it is not possible to say which kidney is the diseased one.

3. The last two propositions being admitted, it follows that, in all advanced cases, incision in the loin and drainage cannot be advocated, as the surgeon is unable to say which side should be incised.

4. In view of these difficulties in diagnosis, it would seem preferable to make an incision in the linea alba, completing the diagnosis with the hand. If the case be a cyst of the kidney, carry the incision upward and complete the operation by enucleating the tumor.

5. This operation is suitable alike for hydro- or pyonephrosis, the danger, of course, being greater in the former.

6. That abdominal nephrectomy by the median incision is a difficult operation, owing to the high position of the tumor and the close relations of the aorta and vena cava, the large size of the renal vessels, and the fact that the tumor is behind both layers of the peritoneum.

7. If a correct diagnosis could be made, abdominal nephrectomy by incision along the linea semilunaris is probably the best operation, but it is not possible to remove very large cysts by incision in the loin.

8. In the case of a weak patient, or one advanced in years, supposing the abdomen to have been opened, the safer procedure might be to open the cyst and drain from the loin. This operation is safer than nephrectomy, but it usually leaves a permanent fistula.

9. It is advisable, in completing the operation of abdominal nephrectomy, to secure drainage by making an opening in the loin.

Prescription for Bronchitis.—According to the *Southern Medical Record*, the following is used by JANEWAY in the treatment of bronchitis:

R.—Syrup of tolu	equal parts.
Syrup of wild cherry	
Tincture of hyoscyamus	
Compound spirit of ether	
Water	

Dose, a teaspoonful.

Prevention of Linea Albicantes of Pregnancy.—F. W. LANGDON (*Cincinnati Lancet-Clinic*, August 9, 1890) believes that the linea albicantes of pregnancy can be prevented by daily inunctions of the abdomen with olive oil, followed by gentle friction with the hand. The inunctions should begin at or before the fourth month of pregnancy, bearing in mind that prevention, not cure, is the object.

[This method of treatment, while by no means new, is not used to the extent that it should be. It adds to the comfort, particularly of primipara, diminishing the sense of distention which is frequently very annoying.—ED.]

Sarcoma of the Breast.—DR. JOSEPH SCHUOLER has published a valuable contribution (*Basle Inaugural Dissertation*) to our clinical knowledge of sarcoma of the female breast. The following are the most important of his conclusions, based on a study of forty-one cases of the disease:

1. Sarcomata constitute about 10 per cent. of all new growths of the female breast.

2. The tumors make their appearance most frequently between the ages of thirty and fifty years.

3. Hereditary influence cannot usually be detected, and there is apparently no causal relation between the function of the gland and the growth.

4. Traumatism, however, seems to play some part in causation.

5. The left mamma is more frequently attacked than the right.

6. As a rule, the first symptom noticed is gradual enlargement of the organ; pain in the early stages is very exceptional. The consistence of the tumor varies from hard to semi-fluid, and it may reach the size of an adult head.

7. Medullary sarcoma cannot be distinguished from medullary cancer until after extirpation.

8. The treatment should be complete excision. Of forty cases operated upon, recurrence took place in 25 per cent. Recidives usually occur within a year after operation, but have been observed as late as nine years after excision.—*Provincial Medical Journal*, Aug. 1890.

Etiology of Tuberculosis of the Intestine.—Dr. Marin Rousseff (*Dublin Journal of Medical Science*, August, 1890), after an exhaustive study of the post-mortem condition of the stomach and intestines in cases of phthisis, formulates the following:

1. Intestinal tuberculosis in chronic pulmonary tuberculosis is caused by the state of the stomach. This organ modified in its structure by interstitial inflammation or by amyloid infiltration can no longer discharge its functions normally, and hence does not act as a barrier against the invasion of the tubercle bacilli.

2. A capital point in the treatment of phthisis should be attention to the state of the stomach; preventing pathological alterations if possible, or treating them if they are present, for intestinal tuberculosis hastens the course of pulmonary tuberculosis.

3. Men more frequently than women are attacked by intestinal tuberculosis, probably because they lead less natural lives, and in consequence are more prone to gastric derangements.

4. The age of the patient, the amount of pulmonary involvement and its duration have but little influence in the causation of intestinal tuberculosis.

5. Pulmonary tuberculosis *per se* cannot excite a gastritis which would lead to tuberculosis of the intestine.

Iodoform and Creasote as an Inhalation in Phthisis.—The following inhalation is recommended by Brunton in the treatment of phthisis:

R.—Iodoform	24 grains.
Creasote	4 minims.
Oil of eucalyptus	8 "
Chloroform	48 "
Alcohol, Ether }	equal parts to make ½ ounce.

To be used in a Robinson's inhaler.—*Virginia Medical Monthly*, August, 1890.

Suppository for Cystitis.—

R.—Iodoform	2 grains.
Extract of belladonna	½ grain.
Cacao butter	45 grains.

Pass this well into the bowel, and morning and night inject into the rectum hot water. If any inflammation of the urethra occurs or is present 1 grain of terpine or salol may be given in pill twice a day.

Permanganate Treatment of Smallpox.—Gawalowski reports the successful employment of baths, colored rose red by the addition of potassium permanganate, in the cure of the eruption of variola and for the reduction of excessive high temperature. The general state under these circumstances was found to improve, the pustules looked better, and the progress of the case went on rapidly toward recovery without any relapses.

Treatment of Laryngeal Phthisis.—Hunt, in the *Annales des Maladies de l'Oreille* for December, 1889, considers the treatment of laryngeal phthisis briefly, as follows: In the early stages, which are always accompanied by anæmia, he prescribes inhalations of oil of tar or creasote, and local applications of chloride of zinc or iron, believing that nitrate of silver is useless at this period. When the catarrhal process is active he uses sedatives or stimulants, as may be indicated, inhalations of mineral astringents, perchloride of iron or an atomized spray of a 1-to-2000 of corrosive sublimate. For the quieting of the cough he thinks the oil of eucalyptus is the best remedy and prefers iodol as an insufflation to all other substances, such as iodoform and lactic acid. The latter he thinks produces pain and inflammation, and increases the cough. When stenosis and œdema of the larynx come on he believes in scarification of the mucous membrane, and also in curetting the surface which is diseased. When stenosis threatens life tracheotomy may be needed.

Ointment for Pityriasis Versicolor.—

R.—Acid salicylic	1 drachm.
Precipitated sulphur	5 drachms.
Vaseline	3 ounces.

Make into an ointment, and before using place the affected part in hot water for several hours, adding one ounce and a half of powdered borax to each gallon of water used. The skin should be well dried before the salve is applied.—*L'Union Médicale.*

Suprapubic Puncture of the Bladder.—According to Dr. Deneffe (*Journal de Médecine de Paris*), the dangers of suprapubic puncture of the bladder in retention of urine are exaggerated, and the operation should not be considered a last resort. He describes a case of retention due to enlarged prostate, and in which the catheter could not be passed, that was punctured seventeen times without harmful effects. After the seventeenth puncture the canula was permitted to remain in place, and ten days later micturition took place through the urethra. Nevertheless the canula was not removed for twenty-nine days. The fistula closed in four days and the patient permanently recovered. Dr. Deneffe has performed the operation on 301 patients with a mortality of 2½ per cent. He believes that sudden retention in cases of stricture or of enlarged prostate is due to spasm of the posterior part of the urethra, that the spasm can be relieved only by removing the urine, and that catheterizing increases the spasm.—*Provincial Medical Journal*, August, 1890.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Philadelphia.

SATURDAY, AUGUST 23, 1890.

THE EDUCATION OF LAWYERS AND PHYSICIANS.

The Medical News has just received a copy of an address delivered by George Gluyas Mercer, LL.M., J.C.D., before the Alumni Association of Haverford College, Pennsylvania, in June, 1889, which is entitled the "American Scholar in Professional Life." In this address its learned author, by a series of quotations taken haphazard from various medical writers, attempts to show that the average medical man of to-day is a mental nonenity possessing so rudimentary an education as to make him little better than a laborer. He also adds his voice to the old cry, that the medical schools of this country are at fault in that they permit men to graduate who do not possess degrees in arts, and fail to insist on a four or five years course, quoting the schools of Germany and England as instances where preliminary study and a course of four or five years are required. While the entire address is most pessimistic in tone we cannot let it pass without at least pointing out some of its faults and fallacies.

No one denies that medical education in the United States is, in the majority of cases, utterly inadequate, and while it is not half so careless in many cases as is that of the law, the greater responsibility of human life, perhaps, makes the teaching worse than the informal courses taken by aspirants for legal honors. Many years have elapsed since a man has been admitted to the ranks of the medical profession simply because he had practised or studied in another man's office; yet in the law this is a most common thing, even in the great cities, where students learn how to draw up a deed or will and little of the real nature of the law. Lawyers' offices are generally notorious loafing-places for young men whose only aim is to learn enough law to pass an entrance examination to the bar. Such individuals perhaps "read law," but never obtain instruction concerning it from a lecturer or teacher. In this much the position of the law to medicine, so far as education is concerned, is that of the individual who must "first cast out the mote in his own eye." In regard to the assertion that a longer time is required abroad than in this country for medical education, qualifying information should have been given. In the best schools in America the student often attends lectures for seven, eight, or nine hours a day, while in England he rarely hears more than four lectures, and most commonly attends but one or two, amusing himself as he pleases during the rest of the twenty-four hours. In Germany the same condition of affairs exists, and in most cases the first two years of so-called study are spent in the beer-garden, or in the pursuit of some still less intellectual enjoyment.

These are mere comparisons, however, of little importance. The question which Mr. Mercer has raised he has failed to answer, or even to offer an idea as to the remedy for the iniquities which he asserts are present. And this is not surprising, in view of the fact that he has not been a teacher in a medical school, and in consequence has but little idea of the expenses connected therewith, independent of the professors' salaries. We doubt if any more expensive educational institution can be found than a well-equipped medical school, pursuing the highest course possible, and in consequence money must be had. The State and nation will not give it, as they do in Germany, nor has America reached an age in which by the accumulations of years the hospitals and universities are richly endowed, as in England. Educational institutions are generally the result of private enterprise, or are so meagrely fed from the State treasury as to be on the verge of inanition. There are, in consequence, but two changes which will remove all ignorance from the medical profession—namely, an improvement in mental calibre

throughout the race, with the elimination of all stupid persons, or, what is more practical, the arousing of the people to the fact that their lives are dependent upon proper medical attendance, which can only be obtained by State contributions to support the medical schools, or by insisting that no one who cannot afford to spend at least four years at college shall attempt to enter the ranks of the profession. If physicians as a class are ignorant, it is because the supply of knowledge, like coal and iron, is always largely governed by demand, and the country doctor can no more invest five years' income in medical centres than the owner of a country store can carry the finest silks instead of the cheapest calicoes.

Mr. Mercer repeats the time-worn assertions that we have an excessive growth of doctors as compared to other countries, but neglects to state that the doors of the law are equally wide open, and that the proportion of lawyers to the population is largely in excess. The one-sided character of the legal mind is, however, thoroughly represented by the closing words of the lecturer in his attack on medical illiteracy, for he asserts that medicine does not necessarily train the mind, in that it is not a science, because "the physician can never know beforehand the precise effect which a drug will produce in a given case, or whether a particular complication will occur in the course of a familiar fever." This lack of knowledge on our part can only be excused when the learned gentleman remembers that as God did not make us all alike, the same rules cannot apply with equal force to each individual. The "uncertainty of the law" depends upon the same variations in mental qualities as the uncertainty of medicine, with the addition that the perverted mental activity of an ignorant judge may give birth to a decision which will at least stand as an important precedent a thousand miles away, or years afterward in a similar case.

Last of all, we are accused of "narrow-mindedness" if we fail to consult with homœopaths, and the author of the paper here loses sight of the very first principle which the law is supposed to uphold, namely, honesty and equity; for if a regular physician consults with a true homœopath the result must be barren, or if the homœopath be one in name only and not in deed, he is a fraud and charlatan with whom a reputable physician has no more right to confer than has a respectable lawyer a desire to take as his colleague a member of the bar whom he regards as devoid of honesty and a disgrace to his profession.

The law deals with facts, medicine with the ever-varying personal equation, an equation generally utterly unknown. Is it not time for the pot to stop calling the kettle black, and for both professions to unite in an effort which will arouse popular feeling to such an extent that our educational institutions will not be dependent upon the whim of a few individuals who may be too lazy, too stupid, or too poor to enter the sacred precincts of any learned profession except through a side door. The people of the United States have provided every child with schooling, and enacted laws preventing illiteracy among those who deal in stoves, or wood, or food, yet they calmly turn their backs, and utterly ignore a lack of knowledge in the individuals who are the only barriers between their dear ones and the grave. The endowment of a hospital is a noble charity, but the endowment of a medical school not devoted to the filling of the professors' pockets, but to the advancement of medicine, is far nobler, since for every moment of suffering saved in a ward, hours of grief, pain, and poverty may be avoided by the skill of thoroughly qualified physicians scattered here and there among the millions of people inhabiting this continent.

IODINE IN OBSTINATE VOMITING.

Every physician who treats his cases intelligently must recognize that he meets with vomiting arising from two opposing states of the stomach or general system. In one case inflammation or irritation of the gastric mucous membrane may exist, while in the other depression and a depraved functional activity prevent the organ from retaining food by some nervous reflex which we do not understand. The vomiting of inflammation may be controlled by aconite in full dose; the vomiting of depression by small or stimulating doses of ipecacuanha.

Within the last few months the tincture of iodine has been highly recommended by a number of writers in the current journals, and they have one and all pointed out that its sphere is in the forms of vomiting due to depression of the stomach. Thus Roques (*Gazette médicale de Liege*) has employed this drug in the vomiting of tuberculosis in its early stages with good results, and recommends its use in chronic gastritis and simple gastric ulcer. He also thinks it of value in the vomiting of pregnancy, and in chlorosis. The drug is not very disagreeable to

take, and produces a sensation of warmth in the stomach which, in some cases, is pleasant to the patient. The tincture should be given, adding ten drops to four ounces of water, one-third of which should be taken immediately after the meal which produces the nausea. Very rarely does this use of the drug produce disagreeable after-effects, but its persistent employment may cause coryza or iodism.

REVIEWS.

Essentials of Anatomy and Manual of Practical Dissection. By C. B. Nancrede, M.D. Third edition, revised and enlarged. Colored plates and woodcuts. Philadelphia: W. B. Saunders, 1890.

The third edition of Nancrede's Anatomy which has just appeared, is a manual of usefulness and value. The publisher has greatly added to the book by the introduction of a large number of beautifully executed plates, which were selected by Dr. Edward Martin, owing to the author's absence from Philadelphia. We have never before seen a book which contained so much in a small space, and yet served as an atlas, quiz-compend, and text-book at one and the same time, which was not so far removed from the grasp of the ordinary student by its cost as to be useless as an aid to general anatomical study. Three editions in less than two years is a success to be envied, and we doubt not that the sales will be doubled during the next year.

CORRESPONDENCE.

"MENTHOL IN DISEASES OF THE AIR-PASSAGES."

We have been requested to publish the following remarks made by Professor E. Fletcher Ingals in the discussion of Dr. S. S. Bishop's paper on "Menthol," read before the Illinois State Medical Society (see The Medical News, July 26, 1890):

"I have had some experience with menthol in the last four or five years, having used it considerably, but I am sorry to say, I cannot corroborate Dr. Bishop's statements in all respects. He recommends strong solutions of menthol, whereas, if I should use such solutions, I would find that, as with any other irritant, the patient would be made worse. I find that hardly more than two or three grains of menthol to the ounce of liquid albolene will be tolerated by the majority of patients. Of course, some patients will stand more, just as one will tolerate bichloride of mercury better than another. I fear you will not obtain the good results from the use of this drug that would be expected from a consideration of the paper of Dr. Bishop, although the author's results have been excellent.

"The use of menthol vapor, as an inhalation, is a different matter, and used in this way others may have results similar to those recorded by the author. I presume this drug does not act very differently from other irritants, such as iodine, sulphate of zinc, or anything else that stimulates the parts. The result is essentially the same whatever drug is employed, providing we get just the right amount of stimulation. Occasionally, perhaps once in four cases, menthol, properly applied, will relieve congestion of the mucous membrane for a considerable length of time, but in the majority of cases it will not do so. In the cases relieved, the swelling disappears and the nose remains comparatively free for an hour or two, but it subsequently stops up, just as it would if cocaine had been employed. In nearly all cases, if used in the strength, even of one and a half or two per cent., the patients are made worse; at least this has been my experience.

"Dr. Bishop spoke of menthol as a good remedy for stopping discharge, and so it is in some cases, but if used a little too strong, the discharge is increased by it, as by other remedies.

"I was glad to hear him speak of the use of the drug in affections of the Eustachian tube and middle ear. I see but little of these affections, as I do not treat diseases of the ear except when they come directly from throat trouble that requires my attention. But in those cases that I do treat I have latterly used about a 2-per-cent. solution (ten grains to the ounce) of menthol in liquid albolene, thrown up behind the palate. I have no difficulty in most cases in getting this directly into the Eustachian tubes. For this purpose I use the spray tubes which are known as Davidson's No. 66, with a tip half an inch long, which can be carried above the point where the palate is drawn firmly against the pharyngeal wall, though with a shorter tip this cannot be done. With a pressure varying from fifteen to forty pounds, which can be regulated at pleasure, the menthol solution can be forced directly into the Eustachian tube, if the nose is held during the application. This pressure, however, is not applied to the middle ear, for the palate will not resist any great force, and the vapor passes backward into the mouth before the pressure gives the patient discomfort. For this application I regulate the pressure according to the sensitiveness of the ear.

"In hay-fever the vapor of menthol gives a little relief to some patients, but, unfortunately, it is not much.

"In laryngeal phthisis this drug has been used for a number of years with the same enthusiasm that has characterized the use of iodoform and many other drugs; and we find reports of many cases of this affection said to have been benefited by menthol. But when we apply it in laryngeal tuberculosis, we find that although there is a little relief at first, an hour or so afterward the patient feels as badly as ever. There are a few cases of laryngeal tuberculosis that are benefited while menthol is being used, but any remedy that we may apply to the larynx, be it menthol or what not, makes very little difference in the actual condition of the parts, unless, by some means, the constitutional disease be checked. Then, and only then, the larynx may be expected to heal; though local applications often appear to hold the disease in check for a short time, and, in so far as they render deglutition easier, they are beneficial.

"Several years ago, at a meeting of the American Laryngological Association, some gentleman spoke of wonderful results obtained in laryngeal tuberculosis from the application of iodoform, which was said to have a specific influence in healing ulceration. At that

time I questioned this so-called specific influence and doubted whether the drug accomplished much, if any, good. To-day, I think, all laryngologists are in accord with the views I then expressed. Menthol in the treatment of this disease has had a history similar to that of iodoform, but thus far it has been found much less useful than the latter."

LONDON.

A Medical Degree for London Students; the Hospitals Committee; the Grievances of Army Medical Officers; Infant Life Insurance; Transplantation of the Thyroid in Myxœdema.

To the Editor of THE MEDICAL NEWS,

SIR: The scheme for the reconstitution of the University of London is still the burning question of the hour, though only a comparatively small number of people take an interest in it, and fewer still really understand it in all its bearings. The agitation originated with the teachers in the Metropolitan schools, who felt that the great majority of students in London had not as fair an opportunity to obtain a degree as they would have in any of the other centres of medical education in the United Kingdom. The original idea was to found a new university on a different plan from the University of London. When the agitation had reached a certain pitch the Government appointed a commission to investigate and report on the subject. Before this body all who objected to the creation of a new and separate university were well represented, and were successful in their efforts, for the Commission reported in favor of altering the regulations of the existing university so as to meet the demands of those who desired a new university. A scheme, with several subsequent modifications, was submitted by the Senate of the University of London, to the licensing bodies, and met with support as well as opposition, and on the whole it seems likely that the latter will prevail.

There are several reasons why it should fail. As at present constituted the degree of the University of London is open to any candidate, no matter in what part of the country he has been educated. Under the new scheme, education *in London* would be compulsory, which is manifestly unjust to the provincial schools, and yet absolutely necessary if the existing university is to satisfy the essential features of the demands of those who originated the agitation. This creates a deadlock which is quite certain to upset the whole scheme, and the sooner the Senate of the University of London recognizes this fact and gives up its opposition to the creation of a new university the sooner will this question be settled. There are other very thorny problems connected with the subject, but the most important matter is that there should be a degree for the attainment of which a certain amount of study in London should be compulsory, and this difficulty can only be met by the establishment of a new university.

The Special Hospitals Committee of the House of Lords is probably by this time thoroughly ashamed of itself and wishing to be released from its undertaking. About twenty meetings have now been held, and, as far as can be judged, the only function of the Committee is to afford one hospital an opportunity to reveal mistakes in management, a proceeding which cannot possibly have any useful effect. Thus far none of the leaders have come forward to give evidence, but inasmuch as there is no likelihood that the meetings of the Committee will have any practical result, this is perhaps not a matter of much moment. The two grievances which have been chiefly aired are, that the hospital appointments are mostly restricted to men who have passed the higher examinations at the College of Physicians and Surgeons here, and are not open to similar qualifications from Scotland or Ireland, and that the out-patient departments damage the general practitioners. In regard to the former point there is not the least likelihood of any change being made, and in regard to the second, the grumblers have not at present made out a case.

The grievances of army medical officers have been much debated of late, and at the instance of the Royal College of Physicians all the leading medical corporations sent a deputation to the Secretary of War, Sir Andrew Clark acting as spokesman. He defined the chief grievance to be the vexed question of rank; it was, he said, that the medical officers of the army having military duties, military responsibilities, and living in a military atmosphere, had not a definite military rank, and that men in other departments of a like constitution had that rank. He made a strong point when he remarked that military rank had, not long since, been granted to the conductor of one of the regimental bands, as this act proved that combatant duties were not essential qualifications for the possession of a military title. He also mentioned the fact that military titles were given to army medical officers in some countries, notably in America, and that no difficulties had been found to arise in consequence. It remains to be seen whether anything will result from the meeting; it is well known that the military authorities are strongly opposed to it, and, further, medical officers in the army have hitherto declared that they did not want military titles. I confess it seems to me hardly possible that the granting of a title will have the effect of converting the service from being very unpopular to a position of popularity, and that some more real change will have to be made if good men are to be attracted to it.

The Bishop of Peterborough's well-meant efforts to reform the law upon the insurance of children do not seem likely to meet with the success which, in my judgment, they deserve. We are told that we must not discourage thrift, and that if we place obstacles in the way of parents putting by something for a rainy day, we will tend to discourage thrift. But it seems to me that until a child is old enough to become a breadwinner there should not be any insurable interest in its life, beyond the amount necessary for funeral expenses, for which purpose insurance is most proper. But this does not meet the views of certain self-constituted philanthropists in the House of Commons, and is in consequence not approved, so that this direct incentive to infant murder will be allowed to go on uncontrolled, and one might almost say directly sanctioned. It is no mere fancy that infants are murdered for the sake of the insurance money, for it was proved beyond doubt a year or two ago by some very gross instances, but the chief culprit died before she could be brought to trial.

Mr. Victor Horsley advocated some few months ago

transplantation of the thyroid in cases of myxœdema and sporadic cretinism. He has returned to the subject lately, and has discovered that a Dr. Bircher anticipated him, at any rate so far as a practical experiment is concerned. In Dr. Bircher's case symptoms of myxœdema having supervened upon removal of the thyroid, he transplanted a portion of a normal thyroid into the abdominal cavity, with the result that the myxœdematous symptoms in great measure disappeared. Some months later a second transplantation was made, again with distinct improvement.

NEW YORK.

To the Editor of The Medical News,

Sir: As the season in which typhoid fever is most prevalent is at hand, I am reminded of an epidemic of that disease which occurred some time ago in the City Insane Asylum on Ward's Island. All the ordinary sources of infection were quickly excluded, and considerable investigation was necessary before it was dis covered that the disease was confined to those patients and their attendants who were permitted to spend much of their time roaming about the northern end of the island. Further inquiry elicited the fact that these people had been accustomed to quench their thirst at a stream situated but a short distance from, and at a lower level than, a small cemetery which had been used at one time for the burial of the typhoid-fever patients from the Emigration Hospital. Such burial places are a constant menace to health, and the question—"How can the city best dispose of its dead? is one of growing importance. The Potter's Field has been removed from place to place: at one time it was on the site now occupied by the Woman's Hospital; at another time it was on Ward's Island; and still later it was transferred to a much more remote point—Hart's Island. The latter place has already a large almshouse population contiguous to this vast resting-place of "the unclaimed dead;" and very little digging on Ward's Island will furnish ample proof of the use formerly made of the land. Certainly the sanitary science of to-day calls for a better state of things, and Dr. A. E. Macdonald, the Superintendent of the City Insane Asylums, recognizing this need, is urging the introduction of cremation as a means of disposing of at least a large number of the bodies now sent to the Potter's Field.

The increased water-supply following upon the completion of the Croton aqueduct has made it possible this summer for many a filthy water-closet in our high tenements to be properly flushed; and if some of this large quantity of water could only be used in sprinkling our dusty streets, there would probably be much less pharyngitis and conjunctivitis among us.

The Board of Health has just published its report for the last year. Among other items of interest I notice that over six thousand quarts of adulterated milk were destroyed, and over one million pounds of fruit and food were condemned and seized. This is a good showing for the Board of Health, but "Little Italy" must have groaned in spirit at being thus ruthlessly deprived of its staple articles of diet. The death-rate for 1889 was 25.13 per 1000, not including stillbirths; and among the 122 deaths reported as resulting from surgical operations, 33 followed laparotomy.

There has been much talk during the last few years about the bad effect upon the public health of the frequent digging up of the streets, required to lay the electric subways and steam-heating pipes, and it has been pretty generally believed, both by the laity and the profession, that such disturbances of the soil are accompanied by malarial manifestation in the neighborhood. If by "malarial" we mean only *bad air*, it is certain that the term is correctly applied, for the freshly uncovered earth, saturated with illuminating gas, gives out a most unpleasant stench. But Dr. Charles N. Dowd, of this city, who has been making a careful bacteriological study of this subject, tells us there is very little reason to believe that genuine malaria is materially increased in this way. He found no marked difference in the bacteriological contents of a gaseous and non-gaseous earth, and the effect of the upturning of the earth without reference to the gas, was to increase markedly the amount of dust, but to augment only moderately the spread of bacteria. He believes that the organism which causes malaria belongs to a different class from those which he studied. The result of uncovering so much ill-smelling earth is chiefly impaired digestion and a feeling of malaise. Although Dr. Dowd's bacteriological research undoubtedly leads to this conclusion, clinical evidence is not wanting to show that malaria is more common after such upturning of the soil; and since the railroads have been making some changes in Morrisania the people there have become painfully aware of this relation between digging and malaria.

NEWS ITEMS.

Medical Examiners of New Jersey.—Governor Abbett, on August 19th, appointed the following physicians, who are to constitute the New Jersey State Board of Medical examiners:

Regular physicians: Dr. William P. Watson, Hudson County, to serve for two years; Dr. George W. Brown, Monmouth County, for three years; Dr. W. L. Newell, Salem County, for one year; Dr. Henry S. Wagner, Somerset County, for one year; and Dr. Hugh C. Hendry, Essex County, for one year.

Homœopathists: Dr. A. Uebalacker, Morris County, to serve for three years; and Dr. A. H. Worthington, Mercer County, for one year.

Eclectic: Dr. Eugene Tiesler, Essex County, to serve for one year.

The Board will meet for organization on Tuesday, September 2d.

A Supposed Case of Cholera in London.—According to Press dispatches from London, a sailor on the steamship "Duke of Argyle," from Calcutta, was landed with Asiatic cholera, on August 17th.

Virchow's Welcome to American Physicians.—Virchow is reported to have extended the following cordial welcome to the American delegates to the International Congress: "We in Germany have great admiration for the American medical world, which to-day excels in

surgery, midwifery, and dentistry. I can say for myself and colleagues that the American contingent will be honored and heartily welcomed. We admire their scientific zeal and begrudge them their extraordinary skill, and shall try to imitate their push and energy. I find these latter virtues in the American student as well as in the finished scientist. My German students generally spend a few semesters deciding what line of medicine they shall follow, while the American student walks into the arena with a fixed purpose and an indomitable determination to accomplish it. This is why your men secure the laurels before their hair turns gray. My friend, Dr. H. Wood, of Philadelphia, will be the speaker for the Americans at the coming Congress. He is sure to do himself and the great city and country from which he comes high credit."

American Public Health Association.—The American Public Health Association will hold its eighteenth annual meeting December 16, 17, 18, and 19, 1890, at Charleston, S. C. The following topics for discussion have been selected by the Executive Committee: Sanitary Construction in House Architecture, including heating, lighting, drainage, and ventilation; Sewage Disposal; Maritime Sanitation at Ports of Arrival; Prevention and Restriction of Tuberculosis; and Isolation Hospitals for Contagious and Infectious Diseases. Papers on various sanitary and hygienic subjects will also be read.

Obituary.—DR. WILLIAM BRODIE, of Detroit, who died July 31st, was a man of national reputation, having been president of the American Medical Association in 1886, as well as of his State Medical Society in 1875. He was born at Frawley Court, England, of Scottish parentage, July 28, 1823. He received his education in this country, graduating in 1850, from the College of Physicians and Surgeons of New York. He settled in Detroit nearly forty years ago, and became one of the best known of its citizens, winning high esteem both socially and professionally.

——DR. J. W. HERON, one of the most prominent medical missionaries in the East, died at Seoul, Korea, August 1st, from dysentery. He was the superintendent of the Royal Hospital at the Korean capital and enjoyed the confidence of the king and of the foreign community.

——GEORGE PIERCE BAKER, M.D., died at Providence, R. I., August 2d, of cancer of the neck and throat. Dr. Baker was born in 1826, at Rehoboth, Mass. He entered Amherst College in 1846, but remained there only two years. His degree in medicine was received from the Harvard Medical School in 1851. He began practice at once in Providence, where he remained throughout the remainder of his life. He was a Fellow of the Rhode Island Medical Society for thirty-nine years, and of the Providence Medical Association nearly as long. He was for two years a vice-president of the former Society, and for nine years a member of its Board of Censors. For several years he was a visiting physician to the Rhode Island Hospital, and more recently one of its consulting staff. During the War of the Rebellion he served as Surgeon on the Peninsula, until prostrated by congestive chills which permanently impaired his health. Dr. Baker was an unpretentious but very thoughtful man. He was a close observer at the bedside, and his wise and kindly advice to the many younger men who called him in consultation was always most valuable. In 1859 he married Miss Lucy D. Cady, of Providence, who died in 1883. He left an only son, who bears his father's name, and is an instructor at Harvard College.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 12 TO AUGUST 18, 1890.

MCCREENY, GEORGE, *Captain and Assistant Surgeon.*—The leave of absence for seven days, granted by order No. 84 (Fort Warren, Mass.), August 13, 1890, is hereby extended fifteen days. —*S. O. 193, Headquarters Division of the Atlantic, Governor's Island, New York City,* August 15, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 16, 1890.

WALES, P. S., *Medical Director.*—Detached from Medical Examining Board and will resume present duty at the Museum of Hygiene.

AMES, H. E., *Passed Assistant Surgeon.*—Ordered as member of Medical Examining Board in addition to present duty.

SAYRE, J. S., *Passed Assistant Surgeon.*—Detached from Navy Yard, New York, and ordered to the U. S. S. "Ranger."

NORTH, J. H., Jr., *Assistant Surgeon.*—Ordered to the Navy Yard, New York.

BARBER, GEORGE H., *Assistant Surgeon.*—Detached from the U. S. Receiving-ship "Vermont," and ordered to the "Pensacola."

VON WEDEKIND, L. S., *Assistant Surgeon.*—Detached from the U. S. "Pensacola," and ordered to the "Vermont."

AUZAL, E. W., *Passed Assistant Surgeon.*—Ordered to temporary duty at the Naval Academy to examine candidates.

FITTS, H. B., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Pinta," to proceed home and wait orders.

STINE, E. P., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Independence," and ordered to the "Pinta."

WHITFIELD, J. M., *Assistant Surgeon.*—Detached from the Monitors, and ordered to the Naval Hospital, Norfolk.

AYERS, JOSEPH, *Surgeon.*—Ordered to the Naval Academy, to examine candidates for admission.

BRIGHT, GEORGE H., *Surgeon.*—Ordered to the Naval Academy, to examine candidates for admission.

SMITH, GEORGE T., *Assistant Surgeon.*—Detached from the Naval Hospital, Norfolk, and ordered to the U. S. S. "Independence."

WHITE, S. S., *Passed Assistant Surgeon.*—Detached from Marine and ordered to the Naval Rendezvous, San Francisco, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM JULY 26 TO AUGUST 12, 1890.

SAWTELLE, H. W., *Surgeon.*—Granted leave of absence for fifteen days, August 8, 1890.

WHEELER, W. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, August 5, 1890.

CARMICHAEL, D. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, August 2, 1890.

PECKHAM, C. T., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, July 28, 1890.

AMES, R. P. M., *Passed Assistant Surgeon.*—Granted leave of absence for fourteen days, August, 1890. To proceed to Shreveport, La., as inspector, August 5, 1890.

KALLOCH, P. C., *Passed Assistant Surgeon.*—Granted leave of absence for seven days, July, 1890.

PERRY, J. C., *Assistant Surgeon.*—To proceed to Wilmington, N. C., for temporary duty, July 31, 1890.

SMITH, A. C., *Assistant Surgeon.*—Granted leave of absence for thirty days, August 11, 1890.

YOUNG, G. B., *Assistant Surgeon.*—Leave of absence extended twenty days on account of sickness, August 2, 1890. Upon expiration of leave, to proceed to New Orleans, La., for temporary duty, August 8, 1890.

STIMPSON, W. G., *Assistant Surgeon.*—When relieved at Buffalo, N. Y., to proceed to Norfolk, Va., for temporary duty, August 5, 1890

ORIGINAL LECTURES.

LUPUS ERYTHEMATOSUS. ACUTE VESICULAR ECZEMA OF THE HANDS, AND OTHER DISEASES OF THE SKIN.

A Clinical Lecture
delivered at the Hospital of the University of Pennsylvania.

BY LOUIS A. DUHRING, M.D.,
PROFESSOR OF SKIN DISEASES

GENTLEMEN: This patient is a well-nourished, rather stout woman, with brown hair and eyes, who has a remarkably extensive development of lupus erythematosus, occupying the nose and both cheeks, and extending as far back as the ears. The greater portion of each cheek is involved, and, as is usually the case in this disease, in a symmetrical manner. The well-known "butterfly" form, the body being represented by the nose and the outspread wings by the cheeks, is here not so striking as usual, because of the widespread extent of the disease. The diseased skin is uniformly infiltrated, and is everywhere surrounded with a sharply defined, distinct, very slightly raised, red border. The skin is of a deep red, somewhat violaceous color, with a faint brownish tinge; is harsh and rough with scales, and is also the seat of scanty, dirty-yellowish, adherent, sebaceous crusts, which are less abundant than usual. The skin is manifestly much inflamed, slightly puffed, and warm to the touch. The process is active, and is evidently encroaching on healthy skin, as shown especially by the bright-red, raised border. And yet, nowhere do we find signs of superficial, whitish, atrophy of the skin, usually so characteristic of the disease, but this will probably appear later. The patient states that the affection began two years ago, and, as we see, has made rapid progress. The patch on the cheeks consists of a continuous sheet of disease. Ordinarily the patches are multiple, with more or less sound skin between them. There is considerable burning, which is markedly worse during the period when the process is most active. In almost all cases the disease inclines to spread more or less rapidly for a few weeks, and then to become quiescent for a variable period, and in the patient before us we have that history. The color and the sharp outline, here, suggest the appearance of vascular nævus, but the diagnosis presents no difficulties. Lupus vulgaris is eliminated because of the acutely inflammatory state of the skin and of the uniform distribution of the pathological process, which shows no disposition to form foci.

Where the disease is active and spreading, and the skin sensitive and hot, local treatment is generally attended with difficulties, for the reason that applications of any kind or strength are apt to disagree with the skin. Remedies that are useful in the subacute or chronic stage are here not tolerated, and the list of available applications is small. It must be kept in mind that, in the acute stage, the disease is readily aggravated by injudicious treatment. We must first endeavor to control and reduce the active hyperæmia, and a valuable remedy for this purpose is composed as follows:

R.—Potassium sulphide	. .	5 to 20 grains.
Zinc sulphate	. . .	5 to 20 "
Water	. . . .	4 ounces.
Alcohol	. . . .	½ ounce.—M.

Apply as a wash, and shake before using.

The strength may be augmented or reduced to suit the skin. It should be dabbed on lightly for fifteen or twenty minutes two or three times a day, the sediment being allowed to remain. In the course of a few weeks this will probably prepare the skin for more energetic remedies, such as sulphur ointment or a tarry tincture. The prognosis, in such an extensive and virulent case as the present, is not favorable—at least a cure cannot be expected until after a long period.

PAPULO-SQUAMOUS SYPHILODERM.

This woman, about twenty years of age, exhibits an eruption of large, broad, sharply-defined maculo-papules, of a cherry-red color, some of them covered with slight scales, situated around the neck from ear to ear and extending into the scalp in the form of ill-defined, scaly patches. The lesions are a manifestation of syphilis, being a secondary eruption, the infection (of which there is no history) having occurred probably four or six months ago. The papules are linearly arranged around the neck, so as to resemble a necklace. About the angles of the mouth are syphilitic fissures, and about each ear there is a large, painful, fissured papule. There is also some glandular engorgement, post-auricular and epitrochlear. The general health is beginning to fail. The protiodide of mercury, one-quarter of a grain in pill-form, three times a day, and five-per-cent. oleate of mercury ointment to the lesions, will be ordered.

ACUTE VESICULAR ECZEMA OF THE HANDS.

The man before us, aged fifty, a street-car conductor, is suffering with an acute attack of vesicular eczema of the forearms, back of the hands, fingers, and sides of the face and neck, everywhere symmetrical. It began a week ago, and is now fully developed, showing vesicles, some ruptured and oozing, others intact; yellowish crusts; blood-crusts and scratch-marks, seated on a slightly puffed, inflamed skin. One of the best forms of treatment for such a case is a salicylic acid plaster, as the following:

R.—Salicylic acid	. . . .	15 grains.
Powdered starch	. . .	2 drachms.
Zinc oxide	. . . .	2 "
Cosmoline	. . . .	4 " —M.

This should be freely applied three or four times daily, the parts being well covered with the paste, to protect

the skin and exclude the air. Should this not prove decidedly beneficial in a few days, black-wash, followed by oxide of zinc ointment, will be advised. Internally, a tonic, saline aperient mixture will probably prove of value. A drachm and a half of sulphate of magnesium and one grain of sulphate of iron in a gobletful of water, to be taken a half-hour before breakfast, daily, may be prescribed for the next week or two.

VESICULAR ECZEMA OF THE HANDS AND FINGERS.

This youth, seventeen years of age, has a similar form of extensive vesicular eczema upon his hands and fingers, and symmetrically developed. It is subacute, and he states that it is of eight years' standing. During this period he has never been free from it, although, as is almost always the case, the disease has been better and worse from time to time, and it incapacitates him for any manual labor or occupation. Here a more stimulating form of treatment is indicated, and a calomel ointment, twenty or thirty grains of calomel to the ounce of oxide of zinc ointment, will be ordered. In three or four days, should no improvement take place, an ointment of resorcin, thirty grains, and salicylic acid, ten grains to the ounce, will be substituted, to be followed later by a tarry wash of one drachm of the alcoholic solution of coal-tar to eight ounces of water.

DRY SEBORRHŒA OF THE SCALP.

The young man before us complains of excessive dandruff, and upon examination of the scalp we find typical dry seborrhœa—the common variety of this disease. In mild cases, such as are usually met with, the diagnosis is easy; but in severe cases the affection may resemble squamous eczema or psoriasis. The treatment is generally followed by satisfactory results. An ointment of precipitated sulphur, one or two drachms to the ounce, which is the simplest and at the same time one of the most efficacious remedies, will be prescribed. Resorcin, as an ointment or as a lotion, is also useful, and may be ordered in the strength of from ten to twenty grains to the ounce. Lotions are often more convenient to apply than pomades, and a formula like this may be employed:

R.—Resorcin	. . . . .	15 grains.
Glycerin	. . . . .	10 minims.
Alcohol	. . . . .	15 "
Water	. . . . .	1 ounce.—M.

PUSTULAR ECZEMA.

The baby before us is suffering with a chronic, extensive, highly developed pustular eczema, involving the whole face, the greater part of the scalp, and the forearms and hands. The face is covered with brownish and greenish crusts, together with flat, yellowish pustules and excoriations. Upon the scalp the crusts are greenish. The crusts are to be loosened by soaking with a boric acid solution, after which a salicylic acid ointment, ten grains to the ounce, may be applied three times a day, to be followed in a few days by a mild tarry ointment, one drachm of tar ointment to the ounce. Should this not agree with the skin after a few days' trial, a calomel ointment, fifteen or twenty grains to the ounce, will be ordered. Directions will be given to the mother, who is nursing the babe, as to the general care of the patient. The digestive tract must be watched, and any disorder corrected, for in many cases of infantile eczema the disease will be found to vary with the state of the alimentary canal.

CLINICAL OBSERVATIONS ON THE HEALING OF ASEPTIC BONE CAVITIES BY SENN'S METHOD OF IMPLANTATION OF ANTISEPTIC DECALCIFIED BONE.[1]

BY WILLIAM MACKIE, M.A., M.D.,
ASSISTANT SURGEON TO THE MILWAUKEE HOSPITAL, MILWAUKEE, WIS.

IN a paper entitled, "On the Healing of Aseptic Bone Cavities by Implantation of Decalcified Bone," published in the *American Journal of the Medical Sciences*, September, 1889, Dr. Senn first called the attention of the profession to this method of hastening the repair in defects of bone, the result of either disease or trauma. In this article Dr. Senn gives a complete review of all that had been previously done in this direction, the result of his own experimental research on animals, and the record of ten clinical observations on the treatment of suppurative and of tuberculous osteomyelitis. Since then he has had under treatment, in the Milwaukee Hospital, eleven similar cases. These he has kindly placed at my disposal. Dr. O'Keef, of Oconto, Wis., at a recent meeting of the Brainard Medical Society, reported one successful case; and Dr. Jones, of Red Wing, Minn., has furnished me with an interesting case. These, with one from my own practice, make in all fourteen cases. In literature, as far as I am aware, only two cases are recorded, one by Deaver, of successful secondary implantation, and one by Weir, which resulted in failure. Professor Esmarch, in a letter to Dr. Senn, states that he has used decalcified bone-chips in two cases. In the first some suppuration occurred, and a few of the chips came away; and in the second, a case of necrosis of the shaft of the tibia, he obtained definite healing by the fourteenth day under one dressing.

Before proceeding to give these cases in detail, it would be well to consider briefly the structure of decalcified bone, and the changes which it undergoes when placed in the peritoneal cavity and in bone; also the preparation of the bone for implantation, the operation, and the after-treatment.

Structure of Decalcified Bone.—Decalcified bone is soft, flexible, and elastic, and by boiling can be reduced to gelatin. It constitutes about one-third part of bone, the other two-thirds consisting principally of phosphate and carbonate of lime. Histologically, it is made up of variously arranged lamellæ, apposed and bound together by fibres of white con-

[1] Read before Wisconsin State Medical Society, June 5, 1890.

nective tissue (Sharpey's fibres). The lamellæ at the periphery and around the Haversian canals have a concentric arrangement, and are irregular between the different systems. Interposed between and hollowed from the opposite surfaces of the lamellæ are the Haversian spaces, in which, in the intact bone, are situated the osteoblasts, and from these spaces extend the canaliculi through which they intercommunicate. Thus, decalcified bone is, histologically, an admirable framework for delicate granulating tissue, and this with a minimum amount of material to be removed by absorption.

In order to ascertain the changes undergone by decalcified bone after implantation, I chiselled a rectangular opening, 8 by 4 millimetres, in the compact layer of the tibia of a young dog, and removed the medulla with a sharp spoon. After opening the medullary cavity the hæmorrhage was very free, but was effectually arrested by plugging the cavity with a solid piece of decalcified bone, over which the periosteum was sutured with catgut and the skin with silk.

Fourteen days after this the animal was killed. Examination showed a formation of new bone under the periosteum, where it had been separated from the bone. This was most marked above the opening, where it was 3 millimetres thick, and was entirely absent immediately around the margin. The periosteum was firmly adherent to the implanted bone. On longitudinal section, through the margin of the opening in the compact layer, the implanted bone was found softened, and of a delicate pink color. The medullary cavity was filled by a solid cylinder of new bone below the point of implantation; complete at the upper margin of the opening, and gradually diminishing in thickness in an upward direction and on the side remote from the opening. A transverse section through the middle of the implanted bone showed that about one-third of it remained in the form of a wedge, the base of the wedge corresponding to the opening in the compact layer, and its apex reaching the centre of the medullary cavity, one-third of which had been obliterated by new bone. Immediately surrounding this remnant, and separating it from the new bony formation in the medullary cavity, was a thin layer of granulation tissue, on the medullary side of which could be detected filiform processes of new bone. Microscopical examination showed infiltration of the decalcified bone by small round cells,—osteoblasts,—most numerous at the periphery and gradually diminishing in number toward the periosteal side. At the margin the structure is composed of granulation-tissue; toward the periphery of the implanted bone the cells are arranged in rows between the lamellæ, and in circles around the Haversian system. The changes observed are, removal of the decalcified bone, wholly or in part, by the action of the osteoclasts, and regeneration of the bone by osteoblasts, with or without the formation of granulation-tissue. Similar changes were observed in a thin piece of decalcified bone sutured to the serous coat of the intestine, and examined fourteen days later.

Preparation of Bone-chips.—The bones to be preferred are those with a thick, compact layer, such as the tibia and femur of the ox. They should be fresh, and after removing the periosteum and the medullary tissue, they are to be cut longitudinally into strips about 3 millimetres in width, and placed in a 10- to 15-per-cent. solution of hydrochloric acid. The fluid should be used in large quantity, and changed every twenty-four hours until the process of decalcification is complete, which requires from one to four weeks. The acid is removed by running water, or, better, by a weak solution of caustic potash. The decalcified bone is next cut into small chips, which are placed for twenty-four hours in a 1-to-1000 solution of corrosive sublimate for forty-eight hours, and finally preserved in a saturated solution of iodoform in ether. Before using they are taken from this solution, placed in a piece of aseptic gauze, and the ether and excess of iodoform dissolved out by alcohol. They should then be immersed in a 1-to-2000 sublimate solution, where they should remain until required for implantation, when the surface moisture is removed by rubbing them in iodoform-gauze. If the alcohol be not thoroughly removed, the chips, by imbibition of fluids after implantation, may swell and produce undue tension on the sutures. For the repair of cranial defects, plates of a thickness corresponding to that of the cranium are used. These are prepared by sawing the compact layer of bone into large, thin plates, and decalcifying them as above. Multiple perforations should be drilled in them to permit drainage of the space underneath, and the size and outline of the plate should correspond exactly to the bony defect.

Operation.—As stated by Dr. Senn, "The most essential condition for success in the treatment of bone defects by the implantation of decalcified bone is a perfectly aseptic condition of the tissues to be brought in contact with the implanted bone." These conditions are attained as follows: The field of operation is shaved, and washed with soft-soap and warm water, and then with 1-to-1000 sublimate solution. If time allows, this is done on the day prior to that fixed for the operation, and the parts are meanwhile kept covered by a moist sublimate compress. After the patient is anæsthetized the limb is elevated, the elastic constrictor applied, the field of operation surrounded by towels wrung from a 5-per-cent. solution of carbolic acid, the compress, if

present, is removed, and the final disinfection is always made with alcohol. The seat of the disease is exposed by a free incision down to the bone, and the periosteum with the attached soft parts is reflected. If a sinus exists it serves as a guide; if absent a new bony formation under the periosteum will answer; and in the absence of either the point of greatest tenderness must constitute the guide. The next step consists in exposing the seat of the bone-lesion by chiselling away the outer compact layer, sufficient of which should be removed to allow inspection and direct treatment of the whole cavity. All granulations and diseased tissue are to be removed by a sharp spoon or chisel, during which frequent irrigation with a 1-to-2000 sublimate solution (in cases of tubercular disease, a sherry-colored solution of tincture of iodine in water) should be used, in order to diminish the risk of traumatic diffusion of pathogenic microbes.

All unhealthy and undermined skin or cicatricial tissue should be excised, even at the risk of leaving a defect in the soft tissue covering the bone; and sinuses in the soft tissues should be cleared of granulations by the sharp spoon and thoroughly disinfected and iodoformized. A final irrigation is then made, the cavity is dried and freely dusted with iodoform. Into the cavity thus made, the chips are firmly packed until the level of the periosteum is reached; a catgut drain is introduced at the most dependent point (viewed from the recumbent position) of the cavity, and the periosteum sutured with fine catgut. If hæmorrhage from the soft tissues is expected, the constrictor is at this stage removed; if hæmorrhage is not probable, it is allowed to remain until after the dressing has been applied. If necessary to secure accurate coaptation of the soft parts, buried sutures of catgut are introduced, and the skin is sutured with silk.

Dressing.—The wound is dusted with iodoform, and covered with oiled silk and several layers of iodoform-gauze, which should encircle the limb. The margin of the gauze is guarded by plenty of salicylated cotton, and over this is placed a cushion of sublimated moss and common cotton; the whole being retained in position by a firmly and evenly applied bandage. To secure rest the limb is fixed on a splint and kept in the elevated position for from six to twelve hours.

When there exists a defect in the soft tissues, the chips are firmly retained in the cavity by the pressure of an iodoform-gauze tampon, and if the parts remain aseptic healthy granulations will encroach on the defect and fill it up.

After-treatment.—During the first twenty-four hours the dressing is frequently inspected, and if the discharge has soaked through, those points are covered with salicylated cotton. If, at the end of that time, the dressing is still moist, it is changed; but if dry, it is allowed to remain and infection guarded against by iodoformization and the application of several layers of salicylated cotton. The first dressing, in the absence of any complications, is made between the tenth and fourteenth day, when the sutures are removed. Union will generally be found complete, except a few granulations at the point of drainage. Future dressings are made at intervals of two to three weeks. The patient is confined in the recumbent posture until the site of the bony defect feels firm and is free from pain. This varies from one to four months, in accordance with the extent of the defect, age of the patient, and the regenerative power of the bone.

Case I. *Circumscribed central osteomyelitis of the tibia.*—L. S., aged eighteen years, male, was admitted into the Milwaukee Hospital, March 13, 1889. For the past three years the patient had suffered from pain in the region of the left ankle; the diagnosis of sprain and rheumatism had been made by different physicians, and treatment adopted accordingly, without any benefit. He had been able to walk until within the last few weeks. The symptoms present on admission were swelling and œdema over the lower epiphyseal line of the tibia, with local increase of temperature, and point of greatest tenderness immediately above this line.

Operation: Making a linear incision over the point of greatest tenderness and reflecting the thickened periosteum with the attached soft tissues, the bone was here explored with a drill, and pus found. This exploratory opening was enlarged by a chisel and an abscess-cavity, containing half a drachm of pus, surrounded by osteoporotic bone, was exposed. The removal of all the pus-infiltrated, cancellated tissue necessitated the exposure of the upper surface of the articular cartilage, and a central cavity remained, twice the size of a hazelnut. This was firmly packed with bone-chips.

First dressing at the end of a week; incision healed, except at drain-opening. A week later, on changing dressing, superficial suppuration was present, and, despite daily change of dressing, the infection extended, so that about six days afterward some of the bone chips came away. Repair was complete by the tenth week from operation, the site of which was indicated by a slight depression in the bone.

Case II. *Diffuse osteomyelitis of os calcis.*—J. G., female, aged forty years; admitted into the Milwaukee Hospital, May 10, 1889, with the following history:

About one year ago she stepped hurriedly from a street-car, and alighted upon the rail with her left heel; to this she paid no attention, considering the resulting pain only a simple bruise. The pain, however, continued to increase, and at last, calling in medical aid, treatment for sprain was adopted. This was continued for months, but the pain remained on throwing her weight on the heel. On admission, inspection revealed nothing; there was

no local increase of temperature; the point of greatest tenderness was located in the middle line on the posterior aspect of the os calcis, above the insertion of the tendo-Achillis, and, on comparing the heels, a nodular prominence could also be detected at this point.

Operation: The nodule was exposed by a linear incision which divided the tendo-Achillis longitudinally in the middle line; the thickened periosteum was reflected, with the soft tissue, and the compact layer of bone removed by a chisel, thus disclosing an extensive osteomyelitic focus. After removing all infected tissue, there remained a cavity one inch deep, one-fourth of an inch wide, and three-fourths of an inch long, which was packed with bone-chips. The periosteum and tendo-Achillis were sutured with fine silk and the superficial incision with medium silk. The relief from pain was prompt. The patient left the hospital at the end of three weeks, when firm pressure on the previously tender point did not give the slightest pain, and there has been no return of the disease.

Case III. *Tuberculosis of the knee-joint; resection.*—M. L., a strong, apparently healthy female, twenty-six years of age, with no family history of tuberculosis, has, for the past eight years, suffered from knee-joint trouble. One year ago a layman undertook to effect a cure. This treatment was followed by an acute synovitis, which, after four months' rest in bed, subsided so that the patient was able to get around again. A second attack occurred during the past winter, leaving the knee permanently enlarged. Since March she has been walking on crutches. On admission to the hospital, November 5, 1889, there was found fibrous ankylosis of the knee and uniform enlargement of the joint, which to the examining finger felt firm. No glandular enlargement in the groin.

Operation: Complete resection of the knee-joint, patella included. On section of the tibia, the bone was found highly osteoporotic, and in the inner tuberosity a triangular sequestrum surrounded by granulation-tissue and encased by sclerosed bone. Corresponding to this there was present a caseous deposit in the inner condyle of the femur. Both these were eliminated, and there remained in the condyle a cavity the size of a pigeon's egg, and in the tibia one of half that size. After complete extirpation of the capsule, thorough iodoformization of the wound and ignipuncture of the tibia, both cavities were firmly packed with decalcified bone-chips before bringing the resected ends into apposition. A catgut drain was introduced at either angle of the incision, which was closed by deep sutures of catgut and superficial of silk. The quadriceps and patellar tendons were united by a strong catgut suture. A large antiseptic dressing was applied, and retained by a plaster-of-Paris bandage, in which was incorporated a posterior iron splint extending from the middle of the thigh to the toes. The limb was kept in an elevated position for two weeks. The highest temperature, 101.5° F., was reached the evening of the second day; the following morning it was reduced to 99° F.

No rise in temperature after this date. At the first dressing, on the sixteenth day, the incision had completely healed, except at the points of drainage; sutures removed and plaster-of-Paris dressing reapplied. Twelve days later, the dressing was removed and the incision found completely healed; examination at the end of the sixth week showed well-advanced consolidation, with only three-quarters of an inch shortening. Fixation dressings were dispensed with twelve weeks after operation, and the patient ordered to walk on crutches. This she refused to do until two weeks later, when, to her surprise, she could bear her weight on the limb without pain or inconvenience.

Case IV. *Penetrating wound of the elbow-joint; secondary suppurative synovitis and osteomyelitis of the humerus.*—C. P., male, seventeen years of age; admitted into the Milwaukee Hospital, July 20, 1889, suffering from suppurative synovitis of the right elbow and osteomyelitis of the lower end of the humerus, following a penetrating wound of the elbow-joint four weeks previously. The wound in the soft parts was situated immediately above the external condyle. On the day of admission thorough drainage of the joint was established, and all the infected medullary tissue removed by the chisel and sharp spoon. Everything progressed favorably until the middle of September, when the central osteomyelitis began to extend upward. Toward the end of November two abscesses developed in the upper portion of the arm, one opposite the middle of the humerus anteriorly, the other opposite the surgical neck on the outer aspect. These were incised and drained. In January, the elbow and the lower fourth of the humerus having recovered, the patient assumed the duties of the hospital choreman. The drainage-openings continued to discharge, and for the cure of this chronic central osteomyelitis the following operation was undertaken, November 26th: The shaft of the humerus was exposed at the superficial openings, and two corresponding cloacæ communicating with each other through the medullary cavity were found in the bone. Between these two points the medulla was exposed by chiselling away the outer lamella of sclerosed bone. The disease was limited above by the epiphyseal line to which the upper opening corresponded, and extended downward in the middle of the shaft to the point where the first operation terminated—at the upper boundary of the lower fourth of the humerus. To remove this, more of the outer lamella was chiselled away, so that when all the diseased tissue had been removed there remained a cavity half an inch wide, and spiral in direction, extending from the upper epiphyseal line on the outer aspect, downward and inward, and terminating anteriorly at the upper border of the lower fourth of the humerus. The cavity was filled with decalcified bone-chips, a catgut drain was introduced at the upper angle of the incision, and the wound sutured. The dressing was renewed on the second day, as it had become saturated with blood; weekly dressing thereafter. The arm was kept in the elevated position for four weeks, and everything being healed, the patient was allowed to leave his bed. At the end of six weeks he resumed his duties as choreman, and left the hospital in the latter part

of March. Examination at this time showed general atrophy of the whole upper extremity from non-use; cicatrix perfectly free, and painless throughout; the gutter represented by a very shallow groove, about one-fourth of an inch in width.

In this case implantation of decalcified bone was not practised at first, because the proximity to the suppurative process in the elbow-joint rendered it impossible to keep the parts aseptic. Even in the presence of this condition the osteomyelitis did not begin to extend upward for six weeks, and it is reasonable to infer that the extension was due to incomplete removal, or to latent microbes becoming again active from some unknown exciting cause, and not to reinfection, because repair in the lower fourth of the humerus was complete at the end of the fifth month. It also affords a comparison in regard to the time necessary for repair, with or without the implantation of decalcified bone. In the former, five months were necessary, and in the latter, six weeks sufficed, although there remained throughout the whole extent of the gutter only three-fourths of the compact layer of the humerus.

Case V. *Chronic central osteomyelitis, secondary to compound fracture.*—C. L., male, thirty-eight years of age, sustained, five months ago, a compound fracture of the left leg, in the lower third. Sloughing of the soft tissues over the anterior surface of the tibia occurred about the end of the second week. Union advanced slowly, and at the point of sloughing there remained a small opening, surrounded by granulations and communicating with the medullary cavity of the bone.

Operation, December 31, 1889: The point of fracture was exposed by a linear incision, the periosteum reflected, and the medullary cavity opened by enlarging the opening in the bone by a chisel. Sufficient of the outer lamella was chiselled away to permit complete removal of all the diseased medulla by the sharp spoon. When completed there remained a cavity two inches in length, and half an inch in width, centrally located in the lower fragment. This was packed full of decalcified bone-chips, a drain inserted at the lower angle, and the wound closed in the usual manner.

At the end of the first week the dressing was changed, and sutures removed, when union was found complete, except at the lower angle, where some of the sutures had cut through. Eleven days later, on changing the dressing, some of the bone-chips came away while irrigating; those that remained were firmly embedded in granulation-tissue. This defect healed by granulation, and four weeks later the patient left the hospital cured, the upper part of the cicatrix being free. Where healing by granulation had taken place the cicatrix was adherent with but slight depression in the outline.

Case VI. *Tuberculosis of the ankle-joint; resection.*—W. C., male, nineteen years of age; was admitted into the Milwaukee Hospital, January 21, 1890, with the following history: Father died of asthma, and two sisters of phthisis. At the age of seven patient had measles, followed for three years by sore eyes. As the eyes improved trouble developed in the left ankle, which compelled him to use crutches for three years more. He continued well until about four months ago, when the same ankle began to swell. There was no pain except when stepping hard on the heel. Patient very anæmic; ankle ankylosed and enlarged; no fluctuation; swelling most marked behind the external malleolus; thickening of the lower end of the tibia.

Operation: Resection, with a chisel, of the external malleolus and articular surface of the tibia, and complete removal of the astragalus through a linear incision behind the external malleolus. The primary depots were found in the tibia, from which the disease had extended to the articulation and the astragalus. After removing these depots two cavities remained, one the size of a marble, and the other half that size. These were filled with decalcified bone-chips, and the bones brought into apposition; the incision closed; and the foot placed on a rectangular splint, and retained by plaster-of-Paris. On the third day a change of dressing was necessitated because of saturation with bloody serum; seventeen days subsequently the sutures were removed. Union was complete except at the points of drainage. With the exception of the formation of a small connective-tissue abscess on the inner side of the tendo-Achillis, recovery was uninterrupted. Patient walked on crutches at the end of the second month, and left the hospital two weeks later, greatly improved in general health, and with advancing bony ankylosis of the ankle.

Case VII. *Tubercular osteomyelitis of the tibia.*—A. A., male, twenty-two years old, with no hereditary history of tuberculosis. An abscess developed over the lower half of the tibia twelve years ago. This opened spontaneously, and several small sequestra came away in the discharge, followed in several weeks by cure. Ten years later pain began in the middle of the tibia. This gradually increased, and finally poultices were applied. Two weeks ago, under this treatment, a small abscess opened, the site of which is now indicated by a small sinus on the inner side of the crest of the tibia, and a little below the middle of the bone. Below this point there is a general thickening of the bone with rounding of the crest.

Operation, January 30, 1890: On reflecting the soft tissues a small pin-hole opening leading to the medullary cavity was found in the middle of the anterior surface of the tibia, at the same level, but not corresponding with the opening in the skin. With this as a guide the medullary cavity was opened by a chisel, and found filled with fungous granulations, in which was embedded one small sequestrum. The disease extended upward, and when completely removed, there remained a cavity four inches in length and one in width, centrally located. This was packed with bone-chips, and treated in the usual manner. On the tenth day, when the dressing was renewed, the incision was completely healed, except at the point where the catgut drain had been introduced, and fourteen days

later, on the second change of dressing, this also had closed. The new tissue in the cavity at this point felt firm, and was painless on pressure, and the cicatrix was almost on a level with the old bone. On the thirty-second day the patient was allowed to walk on crutches.

Case VIII. *Osteomyelitis following compound fracture.*—J. L., male, aged twenty-four years, sustained a compound fracture of leg near the middle, ten months ago. Infection occurred: one small piece of bone was discharged: union was slow and accompanied with considerable thickening at the seat of fracture; a sinus surrounded by large œdematous granulations leads to the point of fracture.

Operation, February 5, 1890: After reflecting the soft tissues, the medullary cavity was opened by chiselling away anteriorly the exuberant callus around the sinus. Three small sequestra were found, and after removing all the osteomyelitic tissue a central cavity four inches in length and one in width remained. Bone-chips implanted in the usual manner. On the eighth day the sutures were removed, some of which had cut through at the site of the excised sinus-opening. This healed by granulation and left a slight depression, otherwise the contents of the cavity, in five weeks, were firm and on a level with the surrounding bone. At this time he resumed the use of his crutches, and one week later left the hospital.

Case IX. *Osteomyelitis of the tibia and of the seventh rib.*—E. V., male, eleven years of age, had in the fall of 1888 an acute attack of osteomyelitis in the lower third of the right tibia. This was treated by hot and cold applications without avail; an abscess developed six months later and was opened. The seventh rib was simultaneously involved and treated similarly. From each, several small sequestra came away in the discharge, but the sinuses remained. Since then the patient's general health has greatly improved.

Present condition: Thickening of the lower half of the tibia and undermining of the cutaneous tissue on the inner and anterior surface of the bone in the lower third, over a circular area one and a half inches in diameter, with a central sinus communicating with the medullary cavity.

Operation, March 3, 1890: All of the undermined tissue was excised and the periosteum with the soft parts reflected. The outer compact layer, which was thickened and sclerosed, was chiselled away in an upward direction for a distance of four and a half inches from the epiphyseal line. This gutter, one inch in width, was packed with decalcified bone-chips. After suturing the soft parts a triangular defect remained where the soft tissues were undermined. Here the chips were firmly forced into the cavity by a small compress of iodoform-gauze and the ordinary antiseptic dressing was applied. Two inches of the rib were excised at the same time. Eleven days later the dressing was changed; some of the sutures had cut through, and the chips, left uncovered by soft tissues, were found firmly embedded in a blood-coagulum. The sutures were all removed and a similar dressing reapplied. The chest incision had completely healed. At the second dressing, one week later, some of the superficial chips came away, when those underneath could be seen firmly fixed in the granulation-tissue and partly covered by the same. At the end of the tenth week repair was complete, and there remained a slight depression where healing took place by granulation.

Case X.—*Tuberculosis of the knee; arthrectomy.*—E. K., four and a half years old; child of healthy parents, and with no family history of tuberculosis, was admitted to the Milwaukee Hospital, March 10, 1890, for knee-joint trouble secondary to an injury six months previously. At present the joint is uniformly enlarged, painless, and doughy on palpation. A typical arthrectomy was made on the same day, and the primary depot of infection found in the intercondyloid notch, where limited sequestration had occurred. When this depot was removed there remained a cavity the size of a hazelnut, which was packed with bone-chips. Recovery was retarded by an acute attack of catarrhal icterus, which developed the second day after the operation and lasted about a week. Some suppuration occurred in the superficial incisions, which had completely healed by the end of the twelfth week. There was also at this time some movement in the joint.

Case XI.—*Tuberculosis of the knee; resection.*—J. H., male, seventeen years old, was admitted into the Milwaukee Hospital, April 5, 1890, with the following history: At the age of six he fell from a tree and injured his left knee; some stiffness of the joint remained, but not such as to inconvenience him. About one year ago he sustained a second injury to the same knee, which was followed by a painless enlargement of the articulation. Later the joint became painful on walking, and for the past month the pain has been constant. No hereditary history of tuberculosis.

Present condition: Patient very anæmic: slight rise of temperature at night: pulse small and weak: knee ankylosed and enlarged, with a point of fluctuation on the inner side of the patellar tendon, which is also the point of greatest tenderness.

Operation: Linear incision over the point of fluctuation was followed by the escape of tubercular pus. Digital exploration of the cavity showed that it communicated with the joint, which was opened by the usual transverse incision for resection. An atypical chisel-resection of the ends of the bones was made, during which three tubercular depots were found in the head of the tibia and one in the condyle of the femur. Of those in the head of the tibia, two were situated in the inner half and one in the outer. In the former, tubercular necrosis had occurred, and in the latter the triangular sequestrum was surrounded by sclerosed bone. When these had been removed, two cavities remained, each the size of a walnut, that on the inner side being divided into two parts by a septum of sclerosed bone, and extending downward for about one and a half inches into the shaft to opposite the lower angle of the vertical incision. That in the condyle was the size of a hazelnut. All these were packed with bone-chips before the bones were brought into apposition, provision being made for drainage by strands of

catgut introduced at the angles of the transverse incision and at the lowest point of the vertical. Incisions closed by deep sutures of catgut and superficial of silk. On the following day, the dressing, having become saturated by sero-sanguineous discharge, was changed. The second dressing was made twenty-four days thereafter, when the incisions were found completely healed; the drain-opening at the lower angle of the vertical incision was closed by an aseptic blood-clot; the site of the cavity in the head of the tibia was firm, level with the surrounding bone, and painless on pressure, and consolidation of the bones had commenced. The sutures were removed and a light fixation-dressing of plaster-of-Paris applied, which, at the date of this report, has not been renewed.

Case XII. *Osteomyelitis secondary to compound fracture of the femur.*—J. M. H., aged twenty-nine years, came under my care in May, 1889, for compound fracture of the femur, with extensive comminution of the bone immediately above the condyles. The periosteum was intact posteriorly. The wound in the soft tissues was on the inner side of the thigh about three inches above the epicondyle. Infection followed: a small shred of the underclothing and several small pieces of the bone came away with the discharges. In three months union had progressed so far that the patient could walk with the aid of crutches, and by the end of the sixth month a cane sufficed, yet the sinus at the site of the original wound in the soft parts did not close. On March 10, 1890, he was re-admitted into the Milwaukee Hospital for operation. The point of fracture was exposed by a linear incision on the anterior and inner aspect of the thigh. A small opening was found in the callus, and enlarging this by a chisel, a centrally located sequestrum, surrounded by granulations, was revealed. The sequestrum was extracted and the granulations removed by a sharp spoon, as were also those from the sinus. The cavity was the size of a walnut. This was packed with bone-chips; a small rubber drain was introduced through the sinus at the site of the original wound in the soft parts, and the incision closed by deep sutures of catgut and superficial of silk. A rise of temperature occurred on the fifth day, and on removing the dressing, superficial suppuration was found in the incision. Daily dressings were made, and on the ninth day some of the chips came away. Notwithstanding this the contents of the cavity at the end of the fourth week felt firm, and the incision had healed. The patient was now allowed to walk around, and two weeks later the sinus closed.

Case XIII. *Compound comminuted fracture of the skull* (Dr. Jones's case).—A boy twelve years old. While coasting down a steep incline which crossed a railroad he came in collision with an express train, and sustained a compound comminuted fracture of the skull at the junction of the right parietal and occipital bones. Under the strictest antiseptic precautions the point of injury was exposed by a semilunar incision extending down to the bone, and the periosteum with the soft tissues was reflected. All the fragments of bone were removed, leaving an irregular defect two and a half by three and a half inches. This was accurately closed by three pieces of partially decalcified bone; periosteum sutured with catgut and skin with silk. A small drain was introduced at the lower angle of the incision down to the implanted disks, and a large antiseptic dressing applied. On the second day the drain was removed and on the eighth the sutures, when union was found complete. Eleven weeks after the receipt of the injury the defect was so firm as to justify the boy's return to school. Four months have now elapsed since the accident, and the defect is still as hard and unyielding to pressure as the surrounding bone, with which it is on a level, and is, Dr. Jones believes, ossified. The use of partially decalcified bone was purely accidental, the bone having been taken from the decalcifying fluid at too early a date. The doctor suggests that the partial decalcification may account for so rapid ossification. This is not tenable, for the viability of all the osteoblasts must of necessity have been destroyed and the undecalcified portion of the bone was so much more foreign and inert material to be removed by absorption.

A parallel case to the above, where viable bone-grafts were used, is reported by R. Jaksch:[1]

"A soldier, aged twenty-two years, had a depressed comminuted fracture of the right parietal bone. The opening was cleared, leaving a hiatus of three centimetres in diameter. It was dressed antiseptically. In eight days the skull of a living goose was laid bare, the head was cut off at a single blow, the skull disinfected with ether and sublimate solution, and the whole placed in a 2-per-cent. solution of carbolic acid at a temperature of 38–40° Cent. The calvarium was removed while in the solution and divided into eight pieces, which were laid upon the granulating dura. An iodoform dressing was applied and retained for ten days, when it was removed, and the bone-plates looked pink. Eight days subsequently they showed granulations on their upper surface. A week later the whole surface was granulating, and cure was complete in less than two months."

Contrasting these two cases, the first point to attract attention is the simplicity of Senn's method as compared with the course pursued in the latter case—a very complicated and time-consuming process, with multiple opportunities for accidental infection. Decalcified bone is always ready, or should be so, just as catgut is. There is no gain in time where viable grafts are employed. In the case of Jaksch's patient repair was complete in less than two months and in that of Jones's, in eleven weeks. In the former the time necessary for repair seems shorter, but in reality was not, for the defect there was only 3 centimetres (1 1/5 inches) in diameter, and in the latter it measured 2½ by 3½ inches, nearly three times as large, and this had closed in about four weeks longer, so that the question of time is in favor of decalcified bone. The result was equally good in both cases.

Case XIV. *Osteomyelitis of the head of the tibia.* (Dr. O'Keef's case.)—A young, healthy male, who,

[1] Wiener med. Wochenschrift, September 21, 1889.

while suffering from gonorrhœa, fell and contused the head of the fibula. This was followed by pain in the region of the knee, causing inability to walk. Point of greatest tenderness over the head of the fibula. Tentative drill-exploration of the head of the fibula revealed the presence of pus in the cancellated structure. Part of the compact layer was removed by a chisel, and the medulla by a sharp spoon, leaving only a shell of compact bone. This cavity was packed with bone-chips. Definite healing occurred in thirteen days, under two dressings, and three weeks later the head of the fibula was firm, painless on pressure, without depression, and the cicatrix non-adherent. The patient at this time could walk as well as ever.

The case recorded by Deaver[1] was one of secondary implantation in chronic central osteomyelitis of the lower end of the femur, with sequestration. His colleague, Dr. White, removed the sequestrum and all the infected tissue, leaving a cavity five inches in length and one in width. This was treated in the ordinary manner for seven weeks, but the progress of the regeneration was so slow that Dr. Deaver resolved to try the implantation of decalcified bone-chips. He modified Senn's method somewhat, by placing the bone-chips in successive layers with intervening layers of sterile iodoform. His patient suffered from iodoform intoxication, but this he considers no objection to the method, believing that the beneficial effects of absolutely sterile iodoform, especially in tubercular and syphilitic subjects, more than counterbalance any danger from this source.

This may be questioned by some, but as repair in the soft tissues progresses most rapidly where hæmostasis is absolute, is it not possible that the hæmostatic properties of iodoform may hasten the desired result in cases of implantation? Repair was complete in one month, one-half the time already consumed in treatment without implantation.

Weir's case[2] was one of necrosis of the lower end of the tibia. At the end of two weeks on making the first change of dressing he found that "although everything had apparently gone well, every one of the pieces of decalcified bone had dissolved and come away in the discharge from the wound, and that notwithstanding this there had been some organization of the blood-clot." In none of the above recorded cases did this happen. Even where some of the chips did come away, they were only softened and not dissolved, and if dissolved, how could they be distinguished in the discharge? It is more likely that there was faulty preparation of the chips, probably maceration, or imperfect packing of the cavity. Dr. Weir doubts the success of the operation for two reasons: First, the difficulty of securing a perfectly aseptic condition of the cavity, and, second, because he fails to see how decalcified bone, catgut, or any similar material, can be converted into new bone. He believes that they may serve as a framework—and this is all that Senn claims for decalcified bone; a blood-clot can do no more, and the organization (so called) of this, Weir evidently believes in. He will try by preference the transplantation of viable bone-grafts from the bones of young animals taken from the neighborhood of the epiphyseal line; but to this procedure his first objection—the difficulty of securing an aseptic cavity—is much more applicable than to the use of decalcified bone-chips. In the viable grafts we have, at best, only an aseptic substance, while in the decalcified bone-chips we have a strongly antiseptic one. The latter is surely the more preferable to introduce into a cavity the sterility of which is doubtful; and, further, viable bone-grafts will retain their vitality and grow in an aseptic medium only.

A careful study of the foregoing cases conclusively demonstrates the advantage to be derived from the implantation of decalcified bone in hastening repair in bone cavities. It has been seen that decalcified bone is a porous substance; an aseptic blood-coagulum, as shown by Schleich, is nothing else; and neither is the sponge-graft, as introduced by Hamilton. Hamilton, in his experiments on sponge-grafting, found that the layer of organizing tissue varies from one-eighth to one-tenth of an inch in thickness, and that, when it exceeds this, the granulations become œdematous and flabby. When an artificial framework, such as a blood-coagulum, sponge, or decalcified bone, is introduced, this does not occur, because the advancing granulations find a temporary support until the embryonic tissue becomes sufficiently organized. One strong objection to the method of Schede is the introduction into a cavity, which is at all times difficult to render aseptic, of a substance which is the best culture for pathogenic microörganisms. In decalcified bone we have a strongly antiseptic substance which will tend to destroy any pathogenic microbes that may remain; it is, as Senn terms it, "an antiseptic tampon." Further, the hæmostasis is rendered as complete as possible, only enough blood remaining in the cavity to fill the small spaces between the chips, and thus is met Bergmann's great objection to Schede's method.

The use of viable bone-grafts in pathological processes of bone is unnecessary and objectionable. They are unnecessary because there is no lack of osteogenetic material; the irritative action of the trauma is a great stimulus to the regenerative process, and it has been found, both experimentally and clinically, that if a framework be supplied the defect will become ossified just as soon, if not sooner, than where viable bone-grafts are used. They are also objectionable because sufficient aseptic bone-

[1] The Medical News, Dec. 28 1889.
[2] Ibid., Feb. 1, 1890.

grafts can never be obtained from the site of operation to fill the defect remaining after the removal of all the diseased bony tissue, and there is always the risk of reintroducing a septic graft. Any attempt made to render the grafts aseptic would necessarily destroy the osteogenetic power of the osteoblasts, and would entail the removal by absorption of the inorganic portion of bone, which amounts to two-thirds of the whole. Consequently, there would remain in every case a depression at the site of operation. This objection can be met by the use of viable grafts obtained from other sources, such as the bones of young animals, in the neighborhood of the epiphyseal line, as advocated by Poncet. This is a very complicated process, and consequently opens up many avenues for infection, with a remote possibility of the transmission of some other disease, such as tuberculosis, which has been transmitted by skin-grafts taken from limbs amputated for joint-disease; and if true of skin, why not of bone? Further, in all inflammation of bone accompanied by the formation of new bone, the first change is absorption of the pre-existing bone prior to the osteogenetic process being established. Take, for example, a plastic osteomyelitis: there is first osteoporosis, then osteosclerosis. In other words, bone, before it can be regenerated, returns to its embryonic condition. The same may be safely said of bone grafts—they must return to their embryonic state before their osteogenetic power can assert itself. Such being the case, in the use of decalcified bone two-thirds of the material implanted —the inorganic part of bone—is removed artificially, and nature is aided to this extent. The osteoblasts are wanting, but, so far, those in the surrounding bone, under the irritative action of the trauma, have sufficed to repair the defect completely, when the framework remained; in short, the absence of the osteoblasts is more than counterbalanced by the diminished absorption rendered necessary.

MEDICAL SCIENCE IN CHINA.[1]

BY EDWARD PAYSON THWING, M.D., PH.D.,
OF CANTON, CHINA.

THE aim of this paper is to describe some of the Chinese ideas of the nature of disease and the theory of treatment, then to sketch briefly the changes wrought in the past fifty years by the introduction of Western medical and surgical science.

The Chinese Empire has been fitly compared to Lot's wife: ever looking backward; wedded to the past. Confucius taught the nation that its work was not to create but to conserve and transmit. The usages of centuries have crystallized into unvarying forms. Life and thought move on through ancestral grooves, and that which is inquisitive, inventive, progressive, is viewed with suspicion, if not at once rebuked as seditious. In its exact, comprehensive sense, science has no existence here. Theories, speculations, traditions, and superstitions abound, and are seen in astrology, geomancy, and medicine; but that cautious, candid, thorough investigation of facts, which we call scientific study, does not find an ally in the Chinese mind. The people are, moreover, fettered by a language pronounced by Professor Williams to be "the most meagre and tedious of all tongues." Though the most ancient, it is probably the most intractable of all spoken languages, making the Chinese scholar indifferent to other tongues, because it is impossible for him to study them through the medium of his own. All the terminology of chemistry, medicine, and natural history remains in Greek and Latin, but how to adapt technical Western science to the genius of this language is not easy to decide. Professor Williams also points out the indistinctness by which time is expressed; the confusion of common and proper names; the absence of punctuation, paragraphs, sentences, capital letters, and other helpful signs of speech which native conceit forbids and ridicules. Prejudice and ignorance, however, are greater obstacles than linguistic difficulties to the spread of modern science. This will be seen as we turn to the subject of medicine.

The literature, such as it is, is very copious. During my residence in Canton Hospital, I have had access not only to libraries but to other sources of information upon native medicine. One is amazed at the patience and industry of Chinese scholars in collecting observations in various departments of research. One work in materia medica and therapeutics appears in 40 volumes, and 756 authors are quoted on the same theme. Another work on the medical and agricultural uses of plants is printed in 60 volumes with 1715 engravings.

Dissection of the body being forbidden, the most absurd notions concerning anatomy and physiology have prevailed. Food is supposed to pass from the spleen into the stomach. The larynx leads into the heart; the soul is in the liver; and the pit of the stomach is the seat of breath and the source of joy —perhaps true in some cases. The skull is one bone, so are the arm and the pelvis. The right kidney is the gate of life. Each organ is related to one of the five elements: earth, air, metals, fire, or water. Fire rules the heart; metals rule the lungs; water rules the kidney; and so on. There is not a square inch of the body that is nameless. Applications to each region are made according to the guiding dual theory, of action and reaction—*yin* and *yang*. Heat and moisture are the vital principles. The blood and spirits are their vehicles. There are twelve channels of distribution.

[1] Read at a meeting of the Academy of Anthropology, New York, April, 1890.

The study of the pulse is the most important part of the physical diagnosis of disease. In the Peking Medical Museum is a copper model of a man pierced with many holes, and marked with the names of the pulse. There are three wrist-points and twenty-four kinds of pulse at each point of each wrist, so that the native doctor has 144 pulses to study, by which the condition of the body and even the sex of an unborn child are said to be determined. Of these twenty-four varieties, there are the slow and rapid pulse, the rough, the soft, the strong, the weak, the vibrating, the hidden and the impeded. If we find the latter at the first point of the left wrist, we may expect sudden death. If at the second point of the right wrist, water in the stomach is indicated. Seven cautions are given to the practitioner regarding his own quiet breathing and presence of mind, and manipulations. George Barrow, the traveller, was taken ill with cholera morbus, and a celestial Esculapius was called. Solemn as an undertaker, he fixed his eyes on the ceiling. Beginning at the wrist, he proceeded to the elbow, pressing hard with one finger and lightly with the other, as one plays a violin. After ten minutes' fingering, he pronounced the trouble to be gastric and caused by injudicious diet—a pretty good guess.

In taking the temperature of the body, I noticed that a native physician (whom I recently accompanied through the wards of his elegant hospital at Hong Kong) laid the back of his hand, as we do, on the cheek or carotid region. He also showed me the method of preparing the decoctions used internally and externally. Every fire-pot where the liquids simmer is marked, as are the scores of wooden boxes into which the dregs of the mixtures are put for inspection, whether from the animal, vegetable, or mineral kingdom. In one standard work there are 78 substances from the first and 314 from the vegetable kingdom. Mercury and arsenic are used in specific diseases. Ginseng is greatly prized. It is held as a governmental monopoly and gathered by detachments of soldiers. Opium, camphor, rhubarb, and other medicines used by us are found in the Chinese *Pharmacopœia*. There are many inert substances used. One author commends 132 substances from metals and stones, 99 from reptiles, shell-fish, and the like, and from parts of the human body and its exuviæ a great number of things. The entire catalogue numbers 1012.

The land is overridden with quacks. The extravagant street-signs show it, on which the adventurer announces himself as a "physician and surgeon by descent for several generations." Necromancy and fortune-telling are combined with medicine. I have seen many of these impostors sitting out of doors at their divining tables with their credulous dupes about them. It is also believed that the spirits sniff the refuse of the decoctions referred to, and so these are exposed in the streets. Good food and fruit are also spread on tables in-doors to appease the spirits, and mirrors to frighten them away. Burnt charms are taken in tea for cardiac disorders, and in pure water for ulcers and all fevers. Prayer-healing and casting lots in a bamboo tube with 100 sticks; rubbing a part of an idol, corresponding to the part of the body affected, and a multitude of other methods of treating disease cannot here be described.

At the hour of death, the Chinese, like the ancient Egyptians, believe that good and evil spirits seek the departing soul. I heard an attendant calling by the hour to a dying girl in a ward opposite my room in the hospital, a few weeks since, and was told that it was an appeal to the departing spirit to come back. The beating of gongs is common in Chinese homes in which death is near. So it is at fires. I have had evidence of this in two large conflagrations near us. The din was something dreadful.

Anybody can be a doctor here. If you read the books prescribed by the college at Peking and follow the pulse-points of the copper model, you are "a regular." If not, you are an irregular practitioner and may be convicted of homicide if your patient dies. If you prolong or aggravate the disease to increase your fee, the law says that the money is stolen, and if you lose your patient you must lose your head. I saw a pile of bloody heads on the execution grounds the other day, but did not identify any as belonging to doctors. Indeed, the law is dead, and thousands of mischievous heads remain on medical shoulders. Stranger still, the Chinese race increases, in spite of irrational medicine and the utter absence of those sanitary conditions on which we predicate health. The oldest nation on the earth shows no sign of physical decay.

As to surgery, there is none. Acupuncture may be an exception, and also the terrible emasculation practised at Peking, often with fatal results, in connection with the imperial harem, which is described in the papers of the North China Asiatic Society. Surgical interference is opposed by the superstitious notion that dismemberment or mutilation here will remain in the other life a permanent disfigurement. Furthermore, the rarity of drunkenness and the absence of railways and machinery diminish the number of cases requiring treatment by the surgeon. That there is no natural inability on the part of the Chinese to become first-class surgeons is a fact shown by notable examples. Dr. Wong, a classmate of mine, forty years ago, was the first Chinese on whom a foreign medical diploma had been con-

ferred. He was a graduate in medicine of the Edinburgh University, twenty years a successful practitioner, in charge of the Presbyterian Hospital, Canton, part of the time, and died in 1878. Dr. Ato, a colleague, was the first Chinese to acquire at home a knowledge of Western medicine. He performed, in 1847, at this hospital, the first operation with ether, and soon after, with wonderful dexterity and success, removed an enormous tumor, three feet in circumference, from the back, and another as large as the patient's head from the axilla. This latter operation involved careful dissection and the tying of three arteries. The whole was finished in four minutes. He was an ambidexter, excelled as an oculist, acquired a large fortune and was a man of commanding influence.

The changes wrought in the past half-century by Western medical and surgical science are marvellous, and constitute a powerful argument in behalf of medical missions. Dr. Peter Parker opened here in 1835 the first medical mission hospital in China. It has been remarked of him that "he opened the gates of China with a lancet when Western cannon could not heave a single bar!" Thousands of patients flocked to him from seventeen provinces, some consuming months in the journey, and going home with the voice of gratitude uttering his praise. His patients were found from the beggar in rags to the Emperor's household. The popularity of the Presbyterian Hospital was a guarantee of its safety in time of war, so that a British Consul said that he would regard himself securer in this house where I am now writing than in a gunboat on the river.

Dr. J. G. Kerr, now in charge of the Canton Hospital, has seen thirty-five years of toilful service, and stands at the head of the profession in this country. He has had a medical class, male and female, who pay $20 annually for tuition, and study three years. The instruction is wholly in Chinese. He has published many original works and translations of foreign authors. We are working together now for the establishment of an asylum for the insane, something unknown in China. Dr. Swan and Dr. Mary Niles are physicians here, the latter attending more than a thousand of her sex yearly. There is an unlimited field for women physicians, for Chinese females will endure prolonged suffering rather than be attended by men.

I have visited the medical school connected with the Alice Memorial Hospital at Hong Kong, and heard Dr. Thomson lecture in English. At Formosa there is another school where a knowledge of English is a condition of entrance. The course is four years. There has been a great deal of dispensary work ever since Drs. Robert Morrison and Livingstone opened a dispensary for the poor in Macao, seventy years ago. Drs. Colledge and Bradford, of Philadelphia, should also be mentioned as pioneers, as well as Dr. Pearson, Surgeon of the East India Company, at Canton, in 1805, who introduced vaccination into the Empire—an unspeakable blessing in arresting what before had been an annual epidemic of a most loathsome and fatal character. Asiatic cholera has been another fearful scourge, more than 100 deaths a day occurring in a single town, Amoy, for nearly two months, in 1842. Thousands of lives have been saved by the missionaries.

The expressions of gratitude to Christian doctors by their heathen patients are novel and often pathetic. Gratitude is shown, not only by the *Kow-kow—i. e.*, prostration and bumping the head on the earth—but by other acts, as at Foochow, where Dr. Kate Woodhull, a successful operator for cataract, some months ago received a handsome memorial tablet, which was hung up amid the explosion of firecrackers. The inscription read: "She has given her whole heart." One of Dr. Parker's patients requested leave to send a painter to make a portrait, that he might daily bow to it. Dr. Parker's pecuniary gifts were liberal, for he was an official secretary; and he composed an eloquent poem in praise of the medical missionary.

A sufferer from lupus at Kiang-Si, who had spent her all on native doctors and Buddhist priests, seeing the disease spreading over face and neck, went to the temple and told them that they and their gods were frauds. The priests were horror-stricken, and frightened her into the payment of $7.50 in gold, to get which she sold a few remaining personal effects. The failure of their incantations exhausted the last ounce of patience she had. She and her husband returned to the temple, and cursed the gods and the Buddhists to their hearts' content. On their way home they fell in with a former patient of Dr. Douthwaite, whose body and soul had been saved by this kind physician. Three days by wheelbarrow brought them to Dr. Douthwaite, who not only prayed and read the gospel to them, but gave potassium iodide internally and iodine ointment externally. The disease was arrested, and in a month cured. They returned home, renounced idolatry, and led many of their neighbors to do the same. A Christian teacher was sent for; many more of the villagers threw away their idols; a church was organized where the true God was daily worshipped, and the members became missionaries, sending from their own number an evangelist to preach the gospel, which had done so much for their own village, to regions beyond their borders.

There are about sixty mission hospitals and eighty foreign physicians connected with them in this Empire, besides clergymen and assistants who have acquired a practical acquaintance with medicine

after years of service in isolated districts in the country.

In these far-away neighborhoods a knowledge of simple remedies in sickness and emergencies will save many lives, and invest a man with supernatural influence in the eyes of the priest-ridden and quack-denuded people. Shanghai, which I hope to visit shortly, and many other large cities and towns have hospitals, and natives are being taught Western science. Dr. Eldridge, who, under imperial patronage, has sent out more than thirty Japanese practitioners, said to me when in Yokohama, that in nothing had the recent intellectual advance been more satisfactory than in medical science in Japan. The more conservative Chinese are slower to welcome us with our Western ideas, but the leaven is surely working. Ever since Dr. Lockhart, who was a pioneer of 1843, went with Her Majesty's legation to Peking, at the close of the second war, princes of the palace and officers of highest rank have been applicants for relief at the hands of these "foreign devils," as we have hitherto been regarded.

A few weeks ago I was in an inland city, eighteen miles from Canton, where the chief manager of a native hospital came to the missionary physician, confessing the inutility of his own methods. He paid $15 to be rid of hæmorrhoids, and went his way rejoicing. A pagan teacher, speaking of doctors, said recently, in substance, "When you find a thief on his way to your money-drawer do you pray with him? No, you call the police! So, if you are really ill, you want a foreign doctor." A few days ago a message came to the hospital here for help for a woman who was dying in labor. Dr. Kerr promptly responded, and saved both mother and child. "In an arm presentation the mother is left to die." Again, yesterday, he had a similar call. The ignorant midwife was doing nothing, and held one dead child. Two more unborn, and the mother as well, would have died but for Dr. Kerr. A fortnight since, the naval admiral, General Fong, a high mandarin, came to us for relief for his aged mother, hundreds of miles away. One of our skilled woman physicians responded. A long journey and several weeks' absence are involved. It was a suggestive sight as I saw this stately officer and his attendants, in silken robes and gracious speech, soliciting the aid of foreign science, which their own wealth and boasted civilization failed to furnish. It was a type of Asia, herself, waking from the sleep of centuries to feel the flush and throb of a new life. When an elaborate manikin was shown, and certain medical and surgical methods explained, their wonder and admiration were something interesting to study.

But, I have not time or space to recite further incidents, or to record other data as to the introduction of Western science into this long-sealed, hermit-like nation. My time is crowded, and postage is twenty cents an ounce! A long, *heavy* article is, therefore, out of the question. The Chinese Hippocrates of the second century, contemporary of Galen, gave medicine in doses of a pound, and the system which he founded was so popular that it continued one thousand years. I have ventured to give the reader an *ounce* dose, or less, promising more at another time, in reference to the special work in my hands, namely, the establishment, if possible, of an asylum for the insane. No such institution is to be found in the Empire. Such a humane and beneficent enterprise would fitly crown the history of Western medical science, which the last half-century has made so illustrious in this vast Empire of the oriental world.

Presbyterian Hospital, Canton.

CROTON-CHLORAL IN NEURALGIA.[1]

By H. A. HARE, M.D.,

Demonstrator of Therapeutics and Clinical Professor of the Diseases of Children in the University of Pennsylvania.

The use of butyl-chloral hydrate in the treatment of insomnia due to neuralgic pain is resorted to, in my belief, so rarely in this country that I have thought it worth while to call attention to its interesting action and relative value and safety.

Physiological experiment coupled with practical experience has convinced us all that chloral, while it is the best hypnotic for the majority of cases, is not one which will give sleep in painful affections or relieve neuralgias unless it is given in full doses, so full as to be dangerous. At the same time it is very desirable that we should have some preparation at hand which will both produce sleep and relieve pain. At present we use chloral and morphine together—the first for its somnifacient effects: the second to relieve the pain, and also to cause sleep. A very great advantage of butyl-chloral hydrate is its safety. The active dose for many cases of neuralgia is only 5 grains, given in pill-form, yet as much as 40 grains may be used without producing any more noteworthy effects than 20 grains of ordinary chloral so far as the heart and respiration are concerned.

The following case is of interest, as showing its advantages:

M. G., aged thirty-five years, has had, for over two years, a severe supra-orbital neuralgia, varying in intensity, and accompanied by roaring in the ears and loss of appetite and sleep. The cause of the neuralgia rests in the presence of middle-ear disease, with varying amounts of discharge. The Eustachian tubes are widely dilated and relaxed. The neuralgia is always worse when the discharge becomes in

[1] Read before the American Medical Association, Section on Practice of Medicine, Nashville, May, 1890.

any way suppressed, and the branches of the entire trifacial nerve become involved in the painful neuralgic shootings. At this time it is impossible for the patient to go to the front door, as the noise of the street hurts her head so much as to make the pain unbearable. The loss of strength and flesh was considerable, owing to the decrease in appetite and loss of sleep. Five grains of butyl-chloral hydrate were ordered every two hours in pill-form. Six pills were taken, with entire relief of all the symptoms and the attaining of good sleep and a better appetite. The effects of each dose lasted twenty-four hours, and then the pain required another six pills. She had no attacks for some weeks after this, although the ear was not discharging.

Functional insomnia resting upon no known cause also yields to this drug very well, but insomnia due to any advanced systemic lesion, as in phthisis, is not relieved in every instance under its use. The history of cases of phthisis who use the drug is that they sleep well the first night, and lie awake the second night to cough the lungs clear of mucus which has accumulated during sleep and while the nerves are obtunded by the drug. This second sleepless night can be quieted by a large dose, 20 grains, if desired, but I have never wished to run the risk of choking up the lung by preventing expectoration. In the neuralgia of phthisis and anæmia the drug is very serviceable.

Neuralgias of other nerves than the cranial are rarely benefited by butyl-chloral; but it is worthy of note that it may sometimes give relief in such cases by using with it 10 to 15 drops of the tincture of gelsemium.

In migraine, sick headache, and bilious headache, Ringer has recommended it, and in true migraine with hemianopsia it is certainly one of the most useful remedies along with antipyrine and caffeine, cannabis indica and gelsemium.

Curiously enough, while it cures the neuralgia due to a carious tooth, it does not cure toothache.

A great advantage possessed by croton-chloral is the applicability of moderate doses in cases of heart-disease.

A SUCCESSFUL VAGINAL HYSTERECTOMY.

By J. T. BINKLEY, M.D.,

CONSULTING SURGEON TO THE FANNIE PADDOCK HOSPITAL SURGEON TO THE HOSPITAL OF THE SISTERS OF CHARITY; ETC., TACOMA, WASHINGTON.

About the first of May I was called to see Mrs. E. S., aged forty-seven years, a hard-working, fleshy, but cachectic woman, weighing 175 pounds, the mother of four children, of whom the oldest was twenty, and youngest seven years of age.

She was suffering from constant pain, was confined to her room, and had a muco-sanguineous discharge from a cauliflower mass on the posterior lip of the cervix uteri. Her mother had a cancer of the breast removed at the age of forty-five years, and died of recurrence three months later. Her sister, aged thirty-six, now has cancer of the breast. Two physicians had previously examined the case, and declined to treat it. I concluded that I had to deal with a recent cancer, and thought at once of operative measures. Before expressing my opinion, however, I decided to consult my partner, Dr. McKone, who was at the time out of the city. On his return, two weeks later, we examined the case, and he concurred in my opinion. We removed a fragment of the mass, had our diagnosis confirmed by microscopical examination, and decided to do a vaginal hysterectomy, as the uterus was freely movable, and the cervix so much involved that an amputation would not be radical. Her menstrual periods were occurring about once in twenty-three days. June 8th, about two weeks after the next period, was the date decided upon for operating.

The patient was taken to the Fannie Paddock Hospital, and put under preparatory treatment for a few days, Miss Gray, of the Philadelphia Hospital Training School, executing my orders.

We decided upon the method outlined by the late lamented Dr. Hunter in his excellent monograph, "The Technique of Vaginal Hysterectomy."

The excellent coöperation of the hospital officers, and the skill of the nurse made the most thorough antisepsis and asepsis possible. The pubes and vulva of the patient were carefully shaved and scrubbed. She was etherized, and placed in the lithotomy position by the hospital staff, at 10 A.M., June 8, 1890. The parts were again thoroughly washed with a 1-to-2000 bichloride solution; the instruments, previously boiled and immersed in carbolized solution, were conveniently placed, and presided over by Dr. J. J. McKone, and Dr. T. F. Smith, Surgeon of the Northern Pacific Railroad. Dr. Grant S. Hicks, Surgeon of the Marine Hospital, held the limbs and retractors. Dr. Myles gave the anæsthetics. Dr. E. G. Stratton, of Orting, and the nurses, attended to the sponges.

A broad Simon's blade in the vagina exposed the vault of the vagina, which I mopped out with strong carbolized solution, and then curetted the growth, and touched it with pure carbolic acid. After this I grasped the anterior lip of the cervix with vulsella forceps, drew it down firmly, passed a stout silk ligature high up, and made traction downward and backward, both with the forceps and ligature. A semicircular incision was then made in the anterior vaginal vault, after which I carefully dissected with my finger through the cellular tissue between the bladder and wall of uterus, until the peritoneum was reached. An antiseptic plug of absorbent cotton was pushed into the cavity. The cervix was then drawn down and forward against the bladder, and a similar incision made in the posterior vault. The two incisions, however, did not meet, a small isthmus being left on either side of the neck. The posterior attachments were severed with the finger as before. An assistant then made forcible traction on the suture and forceps, while I applied a long jawed Tait's hæmostatic forceps close to the cervix and body, avoiding the ureters, and severed the uterine arteries and tissues of the right side

nearly to the point of the forceps. A second pair of forceps were similarly applied, and the tissue severed on the opposite side. Two other pairs of forceps were applied higher up, between the first forceps and body of uterus, on either side, embracing all of the tissues up to the broad ligaments, which were then severed. Firm traction failing to bring down the uterus, I decided to retrovert it, which was accomplished by passing a curved, male, urethral sound into the cavity of the uterus, and rotating the point backward, bringing the fundus out through the posterior incision. This brought the upper borders of the broad ligaments within easy reach. I hooked them down with my finger, brought them within the jaws of the forceps, and severed the tissues on either side, making a clean cut up to the point of the second forceps, and entirely freeing the uterus, which was then easily delivered. But one bleeding point presented, and this was readily controlled by the seventh pair of forceps.

The cavity was then carefully sponged, the forceps were supported by iodoform gauze, lightly packed around them in the vagina, and by absorbent cotton about the handles externally. Each pair of forceps was firmly tied with silk to prevent slipping, and the patient was transferred to bed.

The time occupied by the operation, including anæsthetization, was one hour and thirty-one minutes. The patient rallied well from the anæsthetic.

The following is a condensed daily report of the case:

June 8. Small portions of lime water and milk, and of water given. At 5 P. M. she had a little pain. Seven ounces of urine drawn, and a suppository of opium and belladonna inserted in rectum. Temperature 98⅖°, pulse 96. Has had several refreshing naps. 10 P. M., pulse 110, temperature 98⅘°.

9th. 4 A. M. Four ounces of urine drawn. Temperature 98⅖°, pulse 112. Restless. Was given a suppository. At 9 A. M. four ounces of urine drawn; face flushed; thirsty; "starts" in her sleep. At 4 P. M. five ounces of urine drawn. At 11 P. M. temperature 101⅕°, pulse 135. Pain in abdomen; tympany. Ordered one drachm of whiskey hourly. Rectal tube gave exit to considerable gas, followed by much relief. Cold to abdomen increases pain.

10th. Temperature 99⅖°, pulse 116. Gas escaping freely through rectal tube. A little nausea. Forceps removed at noon, forty-eight hours after the operation. The gauze came with them, and the vagina was repacked. Patient much relieved, but tympany persists. Passed twenty-three ounces of urine during the twenty-four hours. Turpentine stupes to abdomen.

11th. 1 A. M. Vomiting. Umbilicus protruding. Tympany enormous; much pain. Gave one-fourth grain doses of calomel every half-hour for four hours, followed by two-drachm doses of Epsom salts. Turpentine internally, glycerin suppository, and turpentine enema, all failed to produce a passage. Temperature and pulse remain the same. Urine a little increased in amount.

12th. Tympany and severe pain in abdomen. Feels as if bowels would move, but continued doses of calomel and sulphate of magnesium fail to produce a passage. Gave a dish of corn-meal gruel and molasses, and in one hour the faradic current to the abdomen. A small, semi-liquid movement followed in about an hour, and two more free passages during the day. Temperature and pulse somewhat reduced.

13th. Tympany disappeared; patient much improved.

14th. Patient very comfortable. Quite natural passage from bowels. A slight burning sensation on urinating. Appetite good. Diet: Mush and milk, beef-tea, crackers, tea, and coffee. Slept well.

15th. Temperature 99⅖° to 100⅕°, pulse 91 to 100. More pain on urinating. Removed tampon, gave a douche, and repacked the vagina with iodoform-gauze. Eats and sleeps well.

16th. Appetite good, but cystitis increasing, and bowels loose. Rests fairly well. Temperature and pulse improved. Gave vaginal douche.

17th. A small bedsore appeared on left hip. Cystitis more severe. Bowels loose. Gave an alkaline diuretic.

18th. Eats and sleeps well. Cystitis and bedsore improved. Two grains of quinine every four or five hours. Temperature 98⅖° to 99⅖°, pulse 84. Sat up in bed.

19th. Much improved. Temperature and pulse nearly normal.

Gradually improved up to June 22d, when she sat up about four hours, in an invalid's chair.

On the 29th she was walking about the room, writing to friends, receiving visitors, etc.

She desired to go home, but we thought it wise to keep her in hospital another week. On July 3d, she had two hard chills (the second, I think, was increased by the nurse—a new one—who exposed the patient for her evening douche directly after the first chill) followed by a temperature of 104⅖°, entire loss of appetite, and one of the most violent cases of cystitis I ever saw. She begged to go home "to die." I had her removed, on a stretcher, on July 9th, to her home, where she rapidly improved under the usual treatment for cystitis until July 12th, when I discharged her.

She is now going about, free from pain, but has a slight serous discharge from the vagina. She eats and sleeps well.

FOUR CASES OF DISEASE OF THE MASTOID.[1]

By ROBERT FILLEY M.D.,
of Chicago.

Barker, of London, in a study of abscesses of the brain, states that three-fourths of brain abscesses are in the temporo sphenoidal lobes, and that nine-tenths of subdural abscesses are found in a circle one inch and a half in diameter, with its centre one inch and a quarter behind and one inch and a quarter above the centre of the bony auditory meatus. It might further be said that nearly all these abscesses originate from disturbances in some

[1] Read before the Illinois State Medical Society, May, 1890.

part of the external auditory apparatus. As long as facts substantiate this statement the study of mastoid affections will not cease to be interesting.

I desire to submit the following brief notes of four cases of mastoid affection which have recently come under my care:

Case I.—Mr. J. M., thirty-eight years old, first seen, February 25, 1888. Recommended to my care by Dr. H. T. Byford. The patient had been suffering great pain on the right side of the head, and great sensitiveness, expressed by rigors, when the ear was touched. There was some discharge from the external meatus, and granulation-tissue extended from the meatus to the membrana tympani. The temperature varied from 99° to 101°, and the pulse from 100 to 120. There was not severe pain on pressure over the mastoid region, but a good deal of pain was complained of over the whole of the temporal bone, and extending to the right eye. The distress associated with the eye gave him great concern. No proof of hearing could be elicited on the right side. He was delirious at times, and talked of being poisoned by his family. Though advised to do so, he refused, for some time, to go to the Hospital. With the use of cathartics, and by attention to the external meatus, his condition was somewhat relieved.

On the 17th of March, the following month, he entered St. Luke's Hospital for operative measures. But I determined to wait a day or two, and give him the benefit of the advantages the Hospital possessed over his own home during the interval. I explored anew the external meatus, but found nothing promising there. I explored the nose more thoroughly than was possible in his home, and I was a little less sensitive to his expression of pain. I found the cartilaginous septum eroded on both sides, and in the posterior and upper part of the nose a vast quantity of muco-purulent material. I will add here that I could elicit no history of syphilis. It was denied, and he offered no objective indications of its previous existence. He had a large family, and his wife had had no miscarriages. There was a history of a blow on the head, which I could in no way connect with the existing affection. From the condition of the nose, however, I concluded that constitutional treatment would probably be advantageous. This treatment was begun at once, and his nose was washed out three times a day. Two days later, Monday, his condition was so much improved that the operation was no longer justifiable, and by the following Saturday, seven days from the time of the proposed operation, he was dismissed from the Hospital, and continued under treatment as an office patient. The pulse and temperature became normal. The pain in the eye and in the head over the region of the temporal bone, and the distressing dizziness, disappeared. Still later, the discharge from the middle ear ceased, and the hearing became practically normal. The ulcerated spots on the septum of the nose were healed. The process of cure extended over four months. He has had no return of the difficulty.

The interesting points in this case are the severe pain in the head, requiring confinement to bed for six weeks, the extreme sensitiveness of the ear, and the confusing dizziness, all of which yielded, without operative measures, to intra-nasal treatment, and to persistent constitutional measures, notwithstanding the impossibility of obtaining any specific history.

Case II.—Mr. A. C., aged thirty-three years. Admitted to Hospital, February 10, 1890. About six weeks previously he lost the hearing in right ear; no pain. Two weeks later, ear began to discharge. During the last week pain had been very severe. No evidence of hearing on affected side, and the mastoid region was tender, red, and swollen; there was some discharge from the external meatus, and the membrane was perforated. There was no delirium. The throat gave evidence of previous cauterization, which the patient said was done with nitric acid in London. The pulse averaged 100, and the temperature varied from 99° to 100° F. Fomentations and palliative measures were used for three days without effect.

On February 13, 1890, the usual mastoid operation was performed. The external part of the bone was not rough, and no pus was encountered in reaching the bone. The only variation from the usual proceeding was in the instruments used for perforating the bone. I used for this purpose a modified farrier's knife. The chisel is, in my judgment, much better than the drill for perforating the outer tables of the mastoid. The cut is clean, and the operative field is open to view, which is not the case when we use the ordinary drill devised for that purpose. With the use of this knife, however, the advantage of the chisel is obtained without the sudden blow associated with the chisel, which should certainly be avoided. If the knife is held firmly, and the patient's head kept steady, and a good support be secured for the elbow, the outer plate is very readily perforated. In the present case the antrum of the mastoid was rapidly reached, pus appeared in the field of operation, and water passed in through the opening readily came through the external meatus.

The wound and external meatus were irrigated with 1-to-2000 bichloride solution, and dressed with iodoform-gauze. In the evening of the day of the operation the patient was reading the newspaper; the second day after the operation the temperature and pulse were normal, and discharge from the middle ear had ceased.

This was a typical case of simple abscess of the mastoid cells, uncomplicated by any marked necrosis; and one month from the time of his admission to the Hospital he was discharged, the wound completely healed and the hearing normal. The history is taken from the notes of Dr. J. E. Perekham, then interne in charge of the department at the Hospital. The reason of rapid recovery in this case was the absence of necrosed bone, the suppurative condi-

tion being confined to the soft tissues in the antrum mastoideum and the middle ear.

Case III.—Mr. M. M., aged thirty-three years, bank clerk. Entered the Hospital, March 28, 1889. There was a history of protracted catarrhal affection of the nasal passages with impairment of hearing on each side, but worse on the left. Two weeks previously to his admission he complained of a "cold in the head." Severe pain, worse at night, was experienced in the right ear, and impairment of hearing was marked. There was some muco-purulent discharge from the right ear, and tenderness over the region of the mastoid, extending also in spots over the whole temporal bone. The swelling was insignificant; the pain was considerable, but there was no delirium. Temperature varied from 99° to 100° F., the pulse did not exceed 100.

During the interval between March 28th and April 14th, various emollient applications, constitutional treatment, and free paracentesis of the membrana tympani were tried without relief. The nose received attention, but beyond a puffiness of the inferior turbinated bones there was no disturbance in that region.

On April 14th, with the assistance of Dr. Robert Locke, interne in charge, from whose notes the case is reported, an incision was made in the usual position behind the ear. The bone was rough, and the periosteum was easily separated. The antrum was penetrated with the knife, previously described, making a gutter-like groove just on a level with and a little behind the external bony canal. The penetration of the cells gave exit to a small amount of muco-purulent discharge, and the solution used for the irrigation came from the external meatus. The wound was dressed with iodoform-gauze.

There was no marked relief from the pain over the temporal bone, nor was the temperature influenced. During the first few days after the operation, by closing the external auditory canal, the patient could force air through the opening in the mastoid. The same constitutional remedies were continued for about two weeks after the operation with no satisfactory result. There then appeared a swelling above and somewhat anterior to the ear; May 4th, about three weeks after the opening of the mastoid cells, the patient was again anæsthetized, a deep incision, parallel to but about an inch and a quarter anterior to the primary incision, was made, and the bone was found rough. The lower part of this incision began at the juncture of the upper part of the auricle with the integument of the scalp, and extended upward about an inch. This incision was connected with the wound of the first operation beneath the periosteum, and a strip of gauze was placed under the periosteum to facilitate the passage of irrigating fluids over the rough bone. Both wounds were irrigated with a 3-per-cent. solution of hydrochloric acid. There was no pus found in the second operation, and a steady but somewhat slow improvement followed, discharge from the external meatus ceased, and hearing improved. The pain was less severe, and gradually subsided. The irrigation was continued twice a day, and both wounds were kept open for three weeks. It was not, however, before June 3d—about a month after the second operation—that the temperature became normal, and even then slight elevations occurred regularly every evening till June 12th. June 15th, a little more than ten weeks after his admission to the Hospital, he was discharged. The wounds were completely healed. The perforation in the membrana tympani was healed, and the hearing was better than on the other side; not, however, so good as before the existence of the affection.

I am convinced that irrigation with hydrochloric acid solution rendered very good service here. In fact, I think it was the chief element in the cure. The swelling which appeared in front of the ear disappeared after its use, and no marked improvement was previously obtained. The use of hydrochloric acid solution for irrigation was, I think, first brought prominently before the profession by Dr. Edmund Andrews, of Chicago, in 1887.

Case IV.—Mr. A. P., aged thirty-seven years. Saw the patient for the first time, March 22, 1890, when he was referred to me by Dr. D. T. Nelson. The left ear had been discharging for about two months. He had been in bed during that time, and was very weak. There was no cerebral disturbance. There were distinct redness, swelling, and tenderness over the left mastoid, extending in the direction of the sterno-cleido-mastoid; temperature ranged about 100° F. Examination of bony external meatus showed necrosed bone. He was recommended to the Hospital for operation, but he did not follow this advice until April 3d. At this time, when he entered the Hospital, the tissues extending downward from the level of the external meatus were greatly infiltrated, but gave no clear indication of the presence of pus. The breath was very offensive, and the tongue heavily coated.

On making the primary incision the bone was felt to be decidedly rough; the periosteum was easily separated, and exposure of the denuded bone showed rather a concave instead of a convex surface over the mastoid process, as though some operation had previously been performed there. On pulling the ear forward the sharp spoon slipped readily into the external canal, where the greater part of the diseased bone was located. It was not thought desirable, under these circumstances, to penetrate the cells, as the principal focus of necrosis was in the external meatus. The necrosed bone was thoroughly scraped with a sharp spoon, which was passed into the external meatus from the opening behind the ear. The infiltrated tissues in the neck were explored for pus, but none was found. The patient felt better, slept better, and ate better, after the operation, but it soon became manifest that some outlet would be necessary to relieve the inflamed tissues lower down. About ten days after the operation it was found necessary to make an incision in the tissues of the neck to give vent to a well-defined pocket of pus.

The original wound over the mastoid process and the necrosed tissue in the external meatus, as well

as the wound in the neck, were freely irrigated twice a day with 1-per-cent. hydrochloric acid solution. His mouth was cleaned several times daily with 2-per-cent. chlorate of potassium solution.

The patient rapidly improved so that on the 27th of April he was discharged from the Hospital, to be treated as an out-patient. Apart from the scraping of the bone and the incision to relieve the infiltrated tissue, the irrigation with hydrochloric acid solution was the chief feature of the treatment in this case. I should add that some preparation of mercury was administered, but my conviction is that the benefit obtained was rather due to the hydrochloric acid solution. He is still under observation, but, apparently, no modification of the treatment will be needed beyond the application of a little burnt alum to any fungoid growths which may appear.

MEDICAL PROGRESS.

Cannabis Indica in Gastric Disorders.—GERMAIN SÉE, in *La Médecine Moderne*, has published a long communication upon the action of cannabis indica in dyspepsia and gastric neuroses. His conclusions may be summed up briefly, as follows:

The drug, when employed in the form of the fresh extract, in doses of one grain divided into three equal parts for administration during the day, does not produce toxic symptoms, but is of value in the non-malignant forms of gastric trouble. These may be divided into two groups, namely, those in which there are alterations in the chemical character of the gastric juice, as, for example, hyper- or hypo-acidity; and those in which neuroses of the gastric or intestinal walls are present without modification of the gastric juice. In all these affections, whether dyspeptic or neurotic, we may find painful sensations, localized or radiating, spontaneous, or provoked by the contact of food. The troubles of movement are due to atony and dilatation, or the antiperistaltic state may be due to neurotic disorders. We may have, too, the formation of gases with eructations, and with vertigo, migraine, and similar affections. Under these circumstances Sée finds that cannabis indica does good with extraordinary constancy, diminishing the pain, reëstablishing the appetite, and increasing digestion. Where there is hyper-acidity, Sée considers that the use of full doses of bicarbonate of sodium should be invariably administered in addition to the hemp, and that it should be taken after the ingestion of the meal.

Where atony is marked, cannabis indica does little good alone, but is useful if combined with lavage and hydrotherapy. Where spasmodic gastric movements occur, it is, however, very valuable by itself, and particularly so in the vomiting depending upon nervous disturbance. While it does not prevent the formation of gases in the stomach, nor stop eructations by any direct influence, cannabis indica prevents the uncomfortable distress accompanying this state, generally called pyrosis or "heartburn."

Sée asserts very strongly that gastric digestion is favored by the drug, and that it quiets hysteroidal tendencies, as well as removes melancholia.

In many cases it is necessary to administer other remedies at the same time, such as alkalies in full dose; purgatives, if constipation be present; and, finally, antiseptics to the alimentary canal. Finally, Sée concludes that in this drug we have a veritable gastric sedative devoid of unpleasant narcotic effects.

Treatment of Pulmonary Tuberculosis.—The late DR. BREHMER, who treated cases of phthisis so successfully in his sanitarium at Goerbersdorf, was a strong advocate of the treatment of the disease in sanitaria. Such institutions, he believed, should be situated among the mountains, as the elevation increases the heart's action through diminished atmospheric pressure, and improves nutrition by stimulating the appetite. The locality should be immune from phthisis, and well sheltered from winds, which are especially injurious. Patients may be allowed considerable exercise in the open air, but upon the least fatigue rest is exceedingly important. Dr. Brehmer, believing nutrition to be of great importance, provided his patients with five meals daily, vegetables occupying a prominent place in the dietary. Every patient should also take three pints of milk daily, increasing to four pints if anorexia is pronounced. Wine is useful because it increases the power of the heart and economizes nutrition.

In the symptomatic treatment, dry, irritative cough should be controlled by "psychical influences," and by the drinking of cold water or of hot milk with seltzer. Morphine is indicated only when the cough is accompanied with expectoration and interferes with sleep. Moderate hæmoptysis is checked by the hypodermic injection of morphine, and an ice-bag to the cardiac region. Ergotin may be used if necessary. In profuse hæmoptysis violent coughing is often necessary to dislodge the clots, but if insufficient they may be removed by a finger introduced into the larynx. If there is much weakness and dyspnœa champagne is a useful stimulant. Fever may be reduced by cold to the præcordium, but if this is not effectual antipyrine or antifebrin may be employed. Night-sweats can often be prevented by the ingestion of a glass of milk containing one or two teaspoonfuls of cognac.—*Occidental Medical Times*, August, 1890.

Sterilization of Catgut Ligatures.—DR. GEORGE R. FOWLER (*Medical Record*, August 16, 1890) has had a series of experiments made to determine if boiling in alcohol will sterilize catgut. The results were positive, and, using them as a basis, Dr. Fowler recommends the following method of sterilization: The catgut is wound on ordinary wooden spools which have been boiled in soda solution. The spools are then placed in a fruit-jar, or in a bottle with a glass stopper, alcohol is poured in, and the stopper loosely inserted. The jar is then placed in a water-bath and boiled for an hour. As bacteria will not develop in strong alcohol, the catgut may be kept indefinitely in the fluid, which can be again boiled should there be a suspicion that the gut has become infected.

The Spirometer in Diagnosis.—M. JOAL, of Mont Dore, has made a number of observations in spirometry that lead him to the conclusion that many nasal and pharyn-

geal affections produce a distinct diminution in the capacity of the lungs. Thus, in cases where hypertrophic rhinitis, adenoid tumors of the naso-pharynx, chronic coryza, etc., have been cured, the capacity of the lungs, as measured by the spirometer, is frequently increased by one fourth, and occasionally even doubled. M. Joal has frequently found that public singers, when they complain of fatigue of the voice, or of diminution in its power or range, are suffering from some, perhaps quite unsuspected, disease in the nose or pharynx, and that if this is cured the normal condition of the voice is restored.

He suggests that professional singers should know their own respiratory capacity, and that this should be occasionally tested, so that any diminution may serve to give a warning of possible disease in the nose or pharnyx, which may be the more easily cured because discovered early.—*Lancet*, August 9, 1890.

The Treatment of Ruptured Uterus.—In the treatment of ruptured uterus, Dr. D. Berry Hart writes, that when the presenting part of the child is still in the genital tract, we must deliver in such a way as to avoid upward tension on the uterus, and, therefore, craniotomy or decapitation should be performed. If the rent is not extensive, he recommends either irrigation with weak sublimate solution, drainage, and abdominal pressure; or tamponade of the uterus, vagina, and rent with iodoform gauze, the edges of the rent being approximated by tenacula while the tampon is being applied. If the tear is extensive, and the fœtus or placenta has escaped into the peritoneal cavity, abdominal section is imperative. With regard to the treatment of the rent, suturing is condemned, as it is both tedious and ineffective. The choice is between Prevôt's operation and tamponing, both through the vagina and the peritoneum, with iodoform gauze. Dr. Hart is in favor of the former method, but mentions two cases in which the latter was successful. In conclusion, he expresses the opinion that even in apparently hopeless cases we should give the patient the chance that operative treatment offers.—*Medical Chronicle*, August, 1890.

Errors in the Diagnosis of Specific Fevers.—In a short paper based upon his report to the Glasgow Health Committee, Dr. J. B. Russell (*Glasgow Medical Journal*, July, 1890) calls attention, first, to the frequency with which an incorrect diagnosis is made in fever cases; and, secondly, to the cause of such errors, viz., the lack of proper training of medical students.

To show the frequency of mistakes in the diagnosis of infectious diseases, Dr. Russell has prepared a table of cases sent into the Belvidere Hospital during seven months of 1889. Of the 1499 cases admitted with the diagnosis of one of the various infectious diseases, in 114 the diagnosis was incorrect, and 85 were not suffering from any infectious disease whatever. The greatest number of errors occurred in the cases admitted as enteric and typhus fevers. Of the 42 cases sent in as enteric fever, 14 were cases of pneumonia, and 10 were absolutely non-febrile. Having pointed out the serious results of such mistakes in diagnosis, Dr. Russell shows how imperfect, in the majority of cases, is the student's training in the study of fevers [A fact no less true in this country than in Great Britain.—Ed.], and that many students have never even seen the rashes and other signs and symptoms of specific fevers.—*Medical Chronicle*, August, 1890.

Partial Removal of Diseased Ovaries.—Dr. Martin, of Berlin, only partially removes ovaries not entirely diseased. In some cases he has also resected part of the tube, and made, by suture of the mucosa to the serous coat, a new ostium. Dr. Martin, as the result of his experience, published in Volkmann's *Klinischer Vorträge*, came to the following conclusions: Patients recover perfectly after partial removal of ovaries for localized chronic inflammatory changes, hydrops folliculi, and oöphoritis. Recovery is also complete, in most cases, after the resection of obstructed and otherwise diseased tubes. The after-histories of seventeen patients operated upon by Dr. Martin prove that women with resected ovaries and tubes are not more exposed than other women to further disease of the parts left behind. Menstruation continued in all cases, and some patients conceived. Dr. Martin states that in 1864 Sir Spencer Wells emptied some dropsical follicles in one ovary of a young girl, having just removed its fellow. The girl afterward married and had children.—*British Medical Journal*, August 9, 1890.

Antiseptic Vaginal Injection.—

R.—Bichloride of mercury	. .	4 grains.
Sulphate of copper	. .	15 "
Chloride of sodium	. .	15 "
Tartaric acid	. . .	8 "
Indigo	. . . .	a trace.
Distilled water	. . .	2½ drachms.
Glycerin	. . . .	2½ " M.

This is to be added to one quart of water, and used after labor, if an injection is required.—*Gazette de Gynécologie*, August 1, 1890.

Treatment of Puerperal Convulsions.—In the treatment of puerperal convulsions, Dr. R. T. Trimble (*American Journal of Obstetrics*, August, 1890) advises the administration of veratrum viride, if the patient is plethoric, until its physiological effects are produced. This, if necessary, may be followed by morphine. If the patient is anæmic, it is better to commence with morphine. These remedies should be given hypodermically; the veratrum in doses of from 2 to 5 drops of the tincture, the morphine in doses of from $\frac{1}{6}$ grain to $\frac{1}{2}$ grain. If these drugs fail, give potassium bromide and chloral by the rectum in doses of from $\frac{1}{2}$ to 1 drachm each. Chloroform is useful, and should be given during the convulsion to all cases. Delivery as early as the safety of the mother will permit should be the rule. Forceps-delivery is preferable, if it can be accomplished safely, but turning is better practice in some cases. Venesection is rarely required, as veratrum will accomplish all that can be expected from bloodletting, and more safely. One serious objection to bleeding is that we cannot know how much blood a woman in labor may lose from the uterus.

Bi-hydrochlorate of Quinine for Hypodermic Use.—In the *Bulletin Générale de Thérapeutique* of July 30, 1890,

Beurmann and Villejean recommend the following preparation for the hypodermic use of quinine:

R.—Bi-hydrochlorate of quinine . 70 grains.
Distilled water . . . 2 drachms.—M.

This solution holds 7 grains in each 10 drops, so that 20 drops, or an ordinary syringeful, would give a good dose of the drug.

As the bi-hydrochlorate of quinine is not generally to be had, it is to be made by taking ordinary chlorate of quinine, as it is found in commerce, and preparing the bichlorate in a few minutes by the following process: Add to distilled water enough hydrochloric acid to give it a specific gravity of 1 045 at 60° F. Then take 1 drachm of this acid solution and add to it 1 drachm of the chlorate of quinine. Finally, add to this enough distilled water to make 2 drachms, and filter. This solution is not caustic, since the acid is neutralized by the basic chlorate of quinine, so that the bi-hydrochlorate is not irritating.

Mixture for Diarrhœa.—The following formula is quoted by the *Canada Medical Record*:

R.—Wine of opium . . . 1 ounce.
Tincture of valerian . . 1½ ounces.
Ether . . . . . ½ ounce.
Oil of peppermint . . . 60 minims.
Fluid extract of ipecacuanha 15 "
Alcohol, sufficient to make . 4 ounces.—M.
Dose, for an adult, 30 drops every three hours.

Antipyrine in Cutaneous Affections.—One of the symptoms which is most disagreeable in a large number of skin diseases, is the intense itching or soreness which causes scratching, with consequent injury to the parts involved. Many remedies are now added to the applications usually ordered to allay this troublesome state. Chief among these are carbolic acid, menthol, chloral hydrate, and cocaine, but even these often prove inefficient. According to Blaschko, of Berlin, antipyrine proves a most valuable remedy under such circumstances, and he recommends that for infants the following be given internally:

R.—Antipyrine . . . . ½ drachm.
Simple syrup . . . 1 ounce.—M.
Dose, half a teaspoonful at night before going to bed.

Sometimes larger doses are needed, but excellent results are to be obtained by this means in eczema, urticaria, strophulus, pemphigus, lichen ruber and planus. Not only does it prove palliative, but often curative, probably by preventing scratching. Antipyrine may also be used for hysterical pruritus with advantage, but in adults must be given in full doses and frequently.

Prescription for Cardiac Dropsy.—Fürbringer uses the following in cases of dropsy from valvular insufficiency:

R.—Infusion of digitalis . . 5 ounces.
Citrate of caffeine . . 30 grains.
Tincture of strophanthus . 75 minims.
Solution of potassium acetate 15 drachms.
Extract of glycyrrhiza . . 75 grains.—M.

This amount is to be taken in two days.—*Medicinische-chirurgische Rundschau*, August, 1890.

Treatment of Eczema in Children.—According to the *Centralblatt f. d. gesammte Therapie*, Delapert uses the following in the eczema of children:

R.—Boric acid . . . . 80 grains.
Balsam of Peru . . . 8 "
Vaseline . . . . 1 ounce.—M.

Atypical Whooping-cough.—Dr. Eigenbrödt, of Darmstadt (*Zeitschrift für klinische Medicin*, Bd. xvii. No. 6), believes, (1) that in addition to the typical form of whooping-cough there is an atypical or abortive form: (2) that the abortive form differs from the typical, only in the absence of the whoop during the paroxysms of coughing; (3) that abortive whooping-cough can be distinguished from bronchitis only by the fact of its contagiousness; (4) that the typical form of the disease may be contracted from the atypical, but, (5) that an attack of the latter does not confer immunity from the former. In support of these conclusions Dr. Eigenbrodt cites a number of cases in which attacks of true whooping-cough were clearly traceable to other cases of prolonged cough without the characteristic whoop.

Saccharin Tooth-wash.—The following prescription is quoted by the *Internationale klinische Rundschau*:

R.—Tincture of myrrh)
" " benzoin of each 13½ drachms.
" " cinchona)
Oil of cloves . . . . 15 minims.
Saccharin . . . . ¾ grain.—M.

The Acarus Folliculorum in the Eyelids.—In the *Centralblatt für prakt. Augenheilkunde*, July, 1890, Professor Steida, of Königsberg, notes the occurrence of this parasite in the hair follicles of the human eyelids as a point of scientific interest, but of little probable importance. They have been found on almost all parts of the body, and seem to give rise to no pathological condition. In a postscript he questions the latter point, since in the lower animals a similar parasite does lead to follicular inflammation; and he cites a case where Burchardt found a living acarus in the contents of a Meibomian cyst, and a case of blepharitis in which Majocchi found a whitish secretion on the lid-margin, which contained numerous eggs and led to the discovery of numerous specimens of the acarus in the Meibomian glands. It is altogether probable, therefore, that they are by no means innocuous in the Meibomian and sebaceous glands, and that they may be found to be the cause of many of the obstinate and unexplained cases of inflammation of the lids. The subject seems well worth careful study.

Butyl-chloral in Trigeminal Neuralgia.—According to Liebreich, trigeminal neuralgia may be relieved by the internal administration of butyl-chloral (croton-chloral), which he prescribes in the following formula:

R.—Butyl-chloral . . . 40 to 75 grains.
Alcohol . . . . 2½ drachms.
Glycerin . . . . 5 "
Distilled water { sufficient to make } 4 ounces.—M.

The dose of this is from two to four teaspoonfuls.—*Therapeutic Gazette*, July, 1890.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SATURDAY, AUGUST 30, 1890.

THE PROPER PLACE FOR FOREIGN STUDY FOR AMERICAN MEDICAL MEN.

Human beings are so much like sheep in their habit of following where their predecessors have led that it seems almost useless to attempt to divert their course from the clinics of Vienna or Berlin to those of London, Liverpool, or Edinburgh; yet anyone who has studied both on the continent of Europe and in England must have been impressed with a number of advantages possessed by English study over those offered in still more foreign lands. Very few medical men in this country recognize that the city of London, with its many millions of inhabitants, must possess a corresponding number of cases of disease and injury, and that the number of its hospitals, the thoroughness of its teachers, and the character of the people, all tend to aid in the pursuit of instruction in the cure of disease. There are other advantages, too, which are even more important. First and foremost is the fact that we all use the same language, and call things by the same names; second, the materia medica list is closely allied to our own, and the preparations are almost identical; third, the disease-processes seen in England resemble those seen in America more closely than do the diseases of other parts of Europe, and we can study morbid conditions in our own race instead of in races possessed of different temperaments and habits, as well as food and drink.

The advantage of the mother-tongue is inestimable. Very few Americans who do not possess German blood know enough of the German language to understand the terms used by a rapid lecturer in the Fatherland, and, if they do not, they lose that which they chiefly desire, namely, the minute points of the subject before them. The average American going to one of the Continental clinics receives most of his instruction from docents, or other instructors of a comparatively low grade, simply because he is one of hundreds who throng, not only around the chief, but overflow to the subordinates; while in England, notably in London, the number of eminent men is so great, and the percentage of foreign students so small, that each and every one can sit at the feet of the teacher whose writings are known everywhere in the civilized world. While the student in Berlin or Vienna becomes imbued with the views of the single individual governing a given course, in London he may go from hospital to hospital and obtain different views, and in consequence become a man of broader ideas and greater resource. The fees at the various hospitals are no higher than in Germany, and the student has the privilege of being in the healthiest city in the world, and eating food resembling that which he receives at home, instead of placing himself in the notoriously bad surroundings of a Continental *pension-lege*, and living on food which only a Teuton can withstand.

So infinite are the advantages of London as a medical centre to Continental centres that it seems almost absurd to sing its praises, were it not that so many of our countrymen fail to go there, and the establishment of a post-graduate course, with Jonathan Hutchinson at its head, renders our lack of recognition of our own Fatherland the more culpable.

THE RELATION OF FILTH TO TYPHOID FEVER.

One of the most interesting features connected with the development of what is known as the germ-theory of diseases is the ever-varying opinions expressed, by those best qualified to judge, of the relation of filth to the formation of a specific ailment. At one time, quite in the memory of comparatively recent graduates in medicine, it was taught that the presence of filth alone, without any specific virus, might provoke this disease. Thus, a

very eminent teacher would freqently detail an instance in which some miners who had been killed by an accident, were buried in a lot so situated that the water-supply of several houses became impure, and in these, in consequence, an epidemic of typhoid soon developed. Later than this we were taught that there was no typhoid fever without the presence of a typhoid-fever germ; and now we are informed by Dr. Vaughan, in his able and interesting article, published in the number of THE MEDICAL NEWS for August 16, 1890, that "wherever man pollutes the soil about him, the air that he breathes, and the water that he drinks, with his own secretions, there *enteric fever* will be found." Whether this conclusion is a correct one or not, only further study and wide experience can determine; and so many difficulties stand in the way of its proof that a distinct and positive result cannot be expected while our methods of experimentation are so crude. One of the chief difficulties connected with the study of the subject consists in the sterilization or preparation of the intestinal contents in such a manner as to prevent typhoid germs from growing, while others are allowed to thrive. This is necessary, since it is highly probable that these various germs may so alter the intestinal state that a few typhoid bacilli taken into the mouth in dust or water, and swallowed, may at once find a favorable place for growth. Doubt must always exist, in a case of typhoid fever where nothing but ordinary filth was ingested, as to whether that filth did not by means of the wind, or by other method of contamination, receive typhoid poisons. While it is true that ulcerations of the intestines, and fever, have been produced in man and animals, without the apparent presence of a typhoid bacillus as we know it, or are supposed to know it, we cannot help believing that the mere pollution of water or other ingesta with non-typhoidal filth will not produce this disease, and that the specific cause must be present. No better experiment to prove this can be cited than the epidemic of typhoid fever at Cumberland, Maryland, last winter and spring, which was especially reported to THE MEDICAL NEWS by a correspondent sent to the spot. As will be remembered by most of our readers, the entire drainage of the town was carried directly into the water-supply, and in consequence, for many months, dysentery and diarrhœa prevailed among the population who drank the water supplied by the city, but no typhoid fever was present until an individual came to the town sick with this disease, when it speedily showed itself in an outbreak of a widespread character. The theory of the development of this disease must, therefore, be considered as represented in the following aphorism: No typhoid fever without infection from a previous case of typhoid fever. The ingestion of filth does not cause typhoid fever, but predisposes the patient to the disease by decreasing the vital resistance and affording a field for the growth of the peculiar germ.

CORRESPONDENCE.

TENTH INTERNATIONAL MEDICAL CONGRESS.

To the Editor of THE MEDICAL NEWS,

SIR: The fourth day of the International Medical Congress, Thursday, was devoted to the work of the different Sections. In that of Internal Medicine, diabetes was the main topic, and of course the question of diet was thoroughly discussed. Heart-disease and anæmia were also taken up, and the differential diagnosis between chlorosis, pernicious anæmia, and leukæmia were dwelt upon. In fact, diabetes, tuberculosis, nephritis, and empyema were the subjects to which this Section gave most of its attention.

On Friday morning, Dr. Senn, of Milwaukee, read his paper, "The Diagnosis and Operative Treatment of Bullet-wounds of the Stomach and Intestines." He illustrated it by three experiments on dogs. His claim, as many of your readers know, is that hydrogen gas should be used in all cases of gunshot-wounds of the abdomen to determine whether the gastro intestinal canal is injured, and that unless it be injured, or unless collapse from bleeding is threatened, abdominal section should not be done. His first experiment proved that hydrogen can be forced from the rectum, through the ileo-cæcal valve, and small intestine, and can be ignited at the mouth. His second, that in case the intestine is wounded the gas will pass through the wound, and can be recognized by the tympany and by ignition at the orifice of the wound. In his third experiment, he shot a dog so as to make a number of intestinal wounds, and then by inflating through the rectum with hydrogen, he found each wound, no opening being overlooked. However, though he found the holes in the intestine, the dog died from hæmorrhage.

On Saturday morning the third and last general meeting was held. It was called to order by President Virchow, who read a telegram from Chicago, inviting the Congress to hold its next meeting at the time of the World's Fair in 1893. As Rome had already been decided on the thanks of the Congress were voted to the generous Americans for their kind invitation. Professor Wood, of Philadelphia, read the first paper, on "Anæsthesia," which was published in the THE MEDICAL NEWS August 9th. It was enthusiastically received and the thanks of the Congress were voted to the author. Professor Wood, as your readers know, comes to the conclusion that, in some cases, death from either ether or chloroform is due to heart-paralysis, in others to respi-

ratory paralysis, and that in still others death results from a combination of both.

Professor T. Lauder Brunton, in another paper read before the Congress, decided that in every case of chloroform narcosis resulting in death, respiratory paralysis was the cause, and that if the respiration be closely watched, and if at the first sign of failure artificial respiration be resorted, to no deaths would result. Thus both Professor Wood and Professor Brunton agree that artificial respiration is of the greatest importance as a remedy in collapse during anæsthesia.

Professor Cantani, of Italy, read a paper on "Antipyresis." He said that it has been positively shown that fever may be due to many different causes and is the general reaction of the system to some poisonous material, probably bacterial. In the different kinds of fever we must, of course, look for agents to destroy primarily the cause. In malaria we have such a remedy in quinine. In the cases where we cannot reach the cause we reduce temperature in one of two ways: 1, by abstracting heat, by cold baths, etc.; 2, by diminishing the production of heat by the antipyretic drugs. The object of the system in reacting by a high fever is threefold: 1. The high temperature actually destroys many of the pathogenic bacteria. 2. It increases the resistance of the tissues and the activity of the leucocytes in destroying bacteria. 3. It changes the tissues, making them an unsuitable soil for the growth of pathogenic organisms. If these conclusions are true, fever is a necessary reaction and must not be repressed, for it is better than artificial methods of killing the invading germs. The danger is not from the fever itself, save very rarely, and we should not give internal remedies which prevent the formation of heat. When, however, the temperature rises too high, the cold baths and sponging will greatly relieve the patient, while they will not check the reaction at all—in fact if anything will increase it; thus helping the system in its struggle against the enemy and aiding it in its own exertions. Cantani, therefore, believes that unless we can attack the germ which causes the fever, by an internal medicine, the best therapy is cold applications; and that all the antipyretics are dangerous, because they depress the already struggling system and stop the natural and best method of cure.

Professor Meynert, the famous neurologist of Vienna, read a very able paper on "The Synchronous Action of the Different Parts of the Brain," which, though valuable to the psychologist and specialist, is of little importance to the practising physician.

Professor Stokvis, of Amsterdam, followed with a paper on "Comparative Racial Pathology and the Capability of Resistance of the European in the Tropics." Long-extended study has convinced him that Europeans can be perfectly acclimatized to tropical climates, and that though the dangers to his life then are very great, he can, by close attention to hygiene, reduce the mortality there to the same percentage as at home. Professor Stokvis's studies have shown that the danger lies in the fact that Europeans do not always adjust their mode of living to the climate, but that when they do the results show that the European race is far more resistant to harmful climatic influences than even the natives. On these grounds he prophesies a complete control of all parts of the globe by the European.

Professor Virchow then made his closing address, in which he said that the world has never before seen such a medical meeting as this, in numbers or in the brilliancy of the members. He paid a glowing tribute to the visitors, and described the benefits of such international meetings. He closed with these words: "And now, my dear friends, let us part in the memory of eternal friendship; let us forget all personal feelings, and remember that this is a league of true workers in truth and peace. May we meet in the same spirit in the Eternal City of Rome in 1893."

In the absence of Dr. Guyon, Dr. Billings, of the U. S. Army, responded on behalf of the Americans. He expressed the high appreciation and the thanks of our country for the splendid reception.

The Congress having finished its work, the members are fast leaving the city. At present it is difficult to judge the value of the work of the Congress, and not until the proceedings have been carefully studied is a complete *résumé* possible. Nearly 800 papers were read; some were excellent, a few were poor, and many were mediocre.

Socially, the Congress was a grand success. The great reception in the Park on Monday, the reception by the city authorities in the Rathhaus on Tuesday, were events never to be forgotten. The Section dinners, the balls, and the closing festivity on Saturday, all tended to make friends of strangers, and to impress the minds of the visitors with the beauty of German hospitality. The French were highly flattered when the sound of the Marseillaise rang through the halls of the Rathhaus of Berlin; the Americans were electrified by Yankee Doodle in the same magnificent building, and good-fellowship abounded everywhere. Not an American found the slightest flaw in the social arrangements.

As far as arrangements are concerned, the Executive Committee may well be proud, for they received nothing but praise, and every wheel in the enormous machinery of the Congress worked smoothly. The Circus Renz was a fine place for the general meetings, and the numerous rooms of the Art Exposition furnished excellent quarters to the twenty-two Sections. The rooms were adorned with the finest productions of modern art. Every Section looked more like a palace than the hall of a scientific meeting.

In regard to the benefits to the profession, every member goes home more ambitious and energetic.

If Koch's work, of which he gave us merely a glimpse, stands the tests of further study, we may look for a revolution in the treatment of tuberculosis, and we must be prepared for new discoveries in the exanthemata. Lister indicated the course of surgery: that the utmost cleanliness is our motto, and that the less we interfere and irritate the better, that the air is not a dangerous septic element, and that drainage is only a substitute which we must try to dispense with.

Berlin, August 10, 1890

THOMSEN'S DISEASE.

To the Editor of The Medical News,

Sir: In your issue of August 16th appears a paper by Dr. Harold U. Moyer, of Chicago, upon Thomsen's Disease, in which he takes exception to my views of

this malady, expressed in a paper published in 1886, in the New York *Medical Record*. The author gives, I think, a wrong impression of what I then said, for the existence of the affection, described by Erb, and one or two others, has never been disputed. I still adhere to my original idea, however, that Thomsen's disease, as an entity, is a rare malady, but that in many forms of coarse disease of the brain there are salient motor expressions which are not strictly "hysterical," but belong to what has been called the "Thomsen symptom-complex." In this conclusion I am supported by such observers as Buzzard, of London, C. L. Dana, of New York, and others. I may say, finally, that the interesting case presented by Dr. Moyer is an example of what I mean, and from the symptoms detailed I think it may as well be assumed to be one of those vague conditions of hyperkinesis as anything else. If in my original paper, or now, I have appeared to be conservative, or even hypercritical, it is because I was, and am, heartily opposed to the growing tendency to redundant and uncertain nomenclature, and to the use of meaningless proper names for the designation of varying and erratic groups of symptoms and uncertain pathological states. Allan McLane Hamilton, M.D.

New York, August 19, 1890.

NEWS ITEMS.

Cholera Intelligence.—According to the *Lancet*, the somewhat ominous silence in official quarters as to cholera in Spain has been broken by the announcement that the disease is still prevalent in Valencia, that it has undergone a recrudescence in that province, that there are also cases in the province of Alicante, and, lastly, that the disease has appeared in the province of Badajoz. Badajoz being one of the frontier provinces, the occurrence has led to great activity on the part of the Portuguese authorities, who have always put their main trust in quarantine restrictions, and who have already gone so far as to stop the entrance of Spanish trains into Portugal until the lazarettos and quarantine establishments are fully equipped. They have also stopped the mails, and letters from England intended to be shipped at Lisbon for the Cape have failed to reach that port. Between May 13th and August 2d, 1100 cases of cholera are stated to have occurred in Valencia and Alicante, 56 per cent. of the attacks having terminated fatally. France is still free from the disease, notwithstanding a recent assertion that a case had occurred in Paris. The attack in question was ultimately decided to be one of acute gastro-enteritis. The outbreak of cholera which has occurred in connection with the Mecca pilgrimage seems likely to be one of considerable importance. Stringent measures have been taken at the various ports and quarantine stations on the Arabian coast of the Red Sea to prevent the departure of the pilgrims except after they have undergone quarantine; but this part of the world is, above all others, the one where quarantine restrictions have exhibited their "leakiness"; and it has now been decided to employ a large number of troops to prevent exit from Arabia, and also entrance to Egypt, except by the recognized routes where lazarettos have been established. But the occurrence may come to have very serious significance for Europe, for a number of Bosnian pilgrims will be returning to Austrian ports, and others will endeavor to reach Malta, and even get as far west as Marseilles. It is impossible to form any correct opinion as to the number of deaths which have as yet occurred. Whilst from one source of information it is stated that the largest daily mortality has reached 155, another source gives 500 as the diurnal number of victims.

Legacy to the Medical College of Indiana.—Dr. William Lomax, of Marion, Indiana, has given his estate, valued at $100,000, to the Medical College of Indiana. The desire of the donor was to make the school a department of the Depauw University, at Greencastle, Ind. Failing in this, however, he determined to give the estate directly to the medical school

Obituary.—Dr. J. Adams Allen, of Chicago, Ill., died August 15th, aged sixty-five years. For many years he held the chair of the practice of medicine and the presidency of Rush Medical College, having removed from Kalamazoo to Chicago, in 1859, in order to assume the former position. He edited the *Chicago Medical Journal*, in conjunction with Drs. Davis, Byford, and others, for ten or more years. He was surgeon-in-chief to the Chicago and Quincy Railroad. He published a work on medical examinations in life insurance that ran through several editions, and that was translated and published in Germany.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 19 TO AUGUST 26, 1890.

With the approval of the Acting Secretary of War, leave of absence for four months, to take effect about September 1, 1890, is granted Walter Reed, *Captain and Assistant Surgeon.*—Par. 17, *S. O. 192, A. G. O., Washington, D. C.*, August 18, 1890.

By direction of the Acting Secretary of War, a Board of Medical Officers, to consist of: Joseph V. D. Middleton, *Major and Surgeon;* Clarence Ewen, *Major and Surgeon;* and William E. Hopkins, *Captain and Assistant Surgeon*, will assemble at the U. S. Military Academy, West Point, New York, at 11 o clock A.M., August 27, 1890, or as soon thereafter as practicable, to examine into the physical qualifications of the candidates for admission to the Academy.—Par. 1, *S. O. 192, A. G. O., Washington, D. C.*, August 18, 1890.

By direction of the Acting Secretary of War, Charles F. Mason, *First Lieutenant and Assistant Surgeon*, is relieved from further temporary duty at Fort Logan, Colorado, and will report for duty at his proper station (Fort Washakie, Wyoming).—Par. 3, *S. O. 191, A G O., Washington, D. C.*, August 16, 1890

By direction of the Acting Secretary of War, the retirement from active service, this date, by operation of law, of John Moore, *Brigadier-General and Surgeon-General*, under the provisions of the Act of Congress approved June 30, 1882, is announced. General Moore will repair to his home, Bloomington, Indiana.—Par. 2, *S. O. 191, A. G. O., Washington, D. C.*, August 16, 1890.

Promotion.

Kendall, William P., *First Lieutenant and Assistant Surgeon.*—To be Assistant Surgeon, with rank of Captain, after five years' service, from August 12, 1890.—*Headquarters of the Army, A. G. O., Washington*, August 18, 1890.

Ives, Francis J., *Assistant Surgeon.*—To be Assistant Surgeon, with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1890.—*Headquarters of the Army, A. G. O., Washington*, August 11, 1890.

Retirement.

Moore, John, *Brigadier-General and Surgeon-General.*—August 16, 1890 (Act of June 30, 1890).—*Headquarters of the Army, A. G. O., Washington*, August 18, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, SEPTEMBER 6, 1890. NO. 10.

ORIGINAL ARTICLES.

ONE HUNDRED CASES OF TYPHOID FEVER.[1]

BY R. L. MACDONNELL, B.A., M.D.,

PROFESSOR OF CLINICAL MEDICINE IN MCGILL UNIVERSITY, MONTREAL; PHYSICIAN TO THE MONTREAL GENERAL HOSPITAL.

THE following remarks are based upon an experience of one hundred cases of typhoid fever which came under my observation in the wards of the Montreal General Hospital. The histories have been taken from my case-books, working backward from the present day. No selection has been made, except that I have put aside all incomplete histories, as well as those in which there was any doubt of the diagnosis. Such a plan of selection necessarily raises the mortality-rate, since all fatal cases were fully recorded, while many non-fatal cases escaped mention.

The period covered by these one hundred cases extends over part of the summer services of 1884 and 1885, part of 1886, all of 1887, part of 1889, and the winter service of 1889–90, and includes the severe epidemic of 1886–87, when the hospital authorities placed a large number of fever patients in tents, a necessity to which they had not been forced since the typhus fever visitations of the last generation. In the summers of 1888 and 1889 the number of typhoid cases in hospital at a time was limited to twenty. The one hundred cases, therefore, represent a selection of severe cases: 1. Because the Montreal General Hospital performs the duties of a city hospital, a marine and an immigrant hospital, and admits all sorts of men in all conditions of poverty and exhaustion. 2. Because, being always overcrowded, and the number of admissions latterly being limited, mild cases and those occurring among the fairly well-to-do are refused admission. For the same reason, children whose parents have homes are not often found among the patients, and in children the mortality is lower than in young adults. 3. A cause for high mortality lies in the fact that in the summer a patient is enabled to work longer with the disease in him than he would be able to do in the severe winters of Canada.

Age.—The mean age was 24.8 years. The extremes were 5 and 45. The age of 77 patients was between 20 and 30 years, and but 9 patients were over 30 years. I wish to lay great stress upon the narrowness of the age-limit, for it explains how the disease fails to communicate itself among persons of different ages. I shall refer to this point again.

Mortality.—Sixteen patients died.

Infection.—Is typhoid fever directly communicable? I believe it is, and my reasons for so thinking are as follows:

1. That a large number of house-officers of the Montreal General Hospital have contracted typhoid fever while on duty. During the last twenty years 39 have served on the house-staff, and of these I have been able to ascertain that 4 had typhoid fever before entering. We have, therefore, 35 left; of this number, 7 had undoubted fever in the hospital, and in 2 other cases the diagnosis was not absolutely certain. This makes it plain that 7 out of 35, or 20 per cent. of the house-staff, took fever —a larger number than took diphtheria, with which at one time they were constantly in contact, for of the 39 but 4 took that disease during the period in question. As for nurses, a large number have fallen victims too, though I have not been able to obtain satisfactory information on that point.

2. That not many nurses of experience have escaped contracting the disease at one time or another. The fact that the disease does not usually affect more than one member of a family at a time may be explained by the narrow limits of the age of susceptibility. In a household the fever is likely to pass over the parents and the young children, and attack those members of the family whose age is between twenty and thirty, whose number must necessarily be limited.

3. There are instances of the disease being communicated to patients in hospital suffering from the effects of accidents and from other diseases, as for example the following:

CASE I.—A Swedish sailor, aged twenty-six years, with a cavity in one lung, but no febrile symptoms, was in constant attendance upon the sick in the epidemic of 1887. He took the fever and went through its regular stages, convalescing in the fifth week. Rose rash was well marked.

This coincidence of typhoid fever and pulmonary phthisis as in the preceding case is rare.

CASE II.—A patient, aged sixteen years, who was completely bed-ridden, and whose case was diagnosed as acute anterior poliomyelitis, after being

[1] A paper read before the Medico-Chirurgical Society of Montreal, June 13, 1890.

some months in hospital contracted typhoid fever in a typical form.[1]

Case III.—One of my fatal cases was that of a girl who was admitted to hospital for ulcer of the leg.

Case IV.—A surgical patient in Dr. Shepherd's wards, who had been some months in hospital, contracted typhoid fever. There were cases of fever in the same ward.

Many other examples might be brought forward. These four came under my immediate notice.[2]

Now it might reasonably be asked, If typhoid fever is communicable, why do not more patients in general wards take the disease? and the answer is simple. Because (1) many are protected by age. We see in my 100 cases how the fever stops at the line of forty-five years, while many are younger than the average typhoid age. (2) Many have other diseases, tuberculosis, for instance, which is rarely met in conjunction with typhoid fever. (3) A certain number of cases may have been protected by previous attacks of fever, and a certain number may not be susceptible. (4) Fever is not as likely to spread in a hospital as it is in a private house, because the ventilation is better, the excreta are more carefully disinfected, and better appliances for counteracting infection are at hand.

Typhoid fever would be much more prevalent amongst hospital nurses, were it not for the fact that a certain proportion of them are protected by previous attacks, and that nearly all of them are over twenty-five years of age (the average of my hundred cases) when they begin nursing.

The Skin eruption.—Rose rash was noted in but 51 per cent. of the cases. This is a low figure, and I have no doubt that the rash was more frequently present, and escaped being noted. The rash was present in 11 of my 16 fatal cases, and in 40 of the 84 non-fatal cases. In 6 of the 11 fatal cases in which rash was present it was noted as being very copious. In one case where death resulted from the exhaustion of diarrhœa, the rash closely resembled the eruption of measles.[3] A delicate, uniform, scarlet rash was present in one case, that of a girl of twenty-five.[4] At first I was under the impression that antipyrine was the cause, but I find, on looking up the subject, that these scarlet rashes have been fully described by Jenner, Murchison, and others. Urticaria was present in 3 cases. In one it followed the administration of antipyrine. An outbreak of several pustules on the wrist and arms occurred in a fatal case. This was in 1885, when smallpox was epidemic, and the appearance of the pustules gave rise to much alarm. The autopsy showed that the case was one of true typhoid fever.

The tongue.—Of all the symptoms of typhoid fever the appearance of the tongue is one on which the utmost reliance can be placed, both for diagnostic and prognostic purposes.

Meteorism must be regarded as of the most serious import. It was present in 10 of the 16 fatal cases, and in one of them it seemed to be the direct cause of death, causing upward displacement of the thoracic viscera and direct embarrassment of the respiration.[1] Murchison noted meteorism in 20 out of 21 fatal cases, and Jenner observed it in 18 out of 19 fatal cases.

It was a surprise to me to find that abdominal distention was noted in but 4 of the 84 non-fatal cases. Probably my house-physicians have not thought it necessary to note mere slight fulness of the belly. All observers are agreed, however, that tympanites is a symptom of most serious import.

The treatment of this dangerous complication is most unsatisfactory. I have never been able to convince myself of the efficacy of the customary turpentine stupe, and internal medication has never yielded me satisfactory results. Charcoal, so constantly prescribed is, I believe, perfectly useless. Nor has the passage of a tube given as much relief as might reasonably be expected. Dr. Bell, in my case which was fatal from tympanites, dissuaded me from puncturing through the abdominal wall with an aspirating-needle, on the ground that when, in abdominal sections, the bowel is so punctured gas and fæcal matter escape through the openings for some time after the needle is withdrawn. Cases illustrating the soundness of this advice have been recorded by Curtis.[2]

Enlargement of the spleen.—Since the summer of 1887 I have paid special attention to the observation of this change. The spleen was found during life to be enlarged in 5 of the 16 fatal cases, but in only 7 of the 84 non-fatal cases. I was under the impression that it was clinically demonstrable in a larger proportion of cases. The fact is, that enlargement of the spleen is more often found by the pathologist than by the clinician, and is by no means constantly present. Small enlargements cannot be readily demonstrated, and even when the organ has attained a considerable size a distended abdomen may interfere with its being recognized.

[1] See Montreal Medical Journal, vol. xviii. p. 445.

[2] This is not the experience of others. Liebermeister boldly makes the statement that physicians and nurses who take care of such patients are not more frequently attacked with the disease than are persons who have never seen such cases. "Up to 1865 I have never seen in the hospitals which I visited (Griefswald, Berlin, Tübingen) a single hospital patient, physician, or nurse, attacked with typhoid fever, although such cases are placed in the general wards."

[4] Ibid., p. 295

[1] Ibid., vol. xviii. p. 444.

[2] Annual of the Universal Medical Sciences, 1890.

Dr. Frederick C. Shattuck, of the Massachusetts General Hospital, in his paper on typhoid fever, which is based on an analysis of 129 cases, comes to a similar conclusion.[1]

Fagge, too, states that he believes the organ may be many ounces heavier than the normal without there being any appreciable percussion-dulness over it; and he has discovered that the spleen is not always found swollen after death, even in young subjects who have succumbed when the disease was at its highest.

Diarrhœa.—It would seem that diarrhœa is the exception, and constipation the rule. Diarrhœa was present in but 27 per cent. of all cases, and of these 27 cases 14 were fatal. Only two patients died without diarrhœa, one of pneumonia, and the other of the effects of a miscarriage.

Murchison notes diarrhœa in 93 per cent. of cases in England, M. Barth (quoted by Murchison) in 96 of 101 cases in France, and Shattuck found it in 51 per cent. in Boston. The difference between these figures is remarkable.

Diarrhœa always means danger, and I have become more and more disposed to regard a patient as safe so long as the bowels remain confined.

Intestinal hæmorrhage occurred in 2 of the 16 fatal cases, but in neither was it severe, nor did it appear to be the cause of death. On the contrary, in all the severe cases of hæmorrhage the patient recovered, so that the opinion expressed long ago by Graves to the effect that hæmorrhages were rather beneficial than otherwise seems not far from the truth. Trousseau was also of the opinion that this symptom was less dangerous than was commonly supposed.

Taking all cases together, severe hæmorrhages occurred in 9 patients. Louis reported hæmorrhages in 8 of 134 cases; Jenner in 7 of 21 fatal cases; Murchison found copious hæmorrhages in 3.77 per cent. of his cases; Shattuck found hæmorrhage in 5.4 per cent.

Our high percentage shows the general severity of the cases admitted. It is remarkable from what very severe hæmorrhages a typhoid fever patient can recover.

H. B., aged twenty-four years; admitted under my care on the sixth day of an attack of fever. History of intemperance. Usual fever-symptoms present. Previously to admission there had been a very severe attack of epistaxis. No abdominal pain or distention. On the ninth day there was retention of urine. On the fourteenth there was a sharp attack of diarrhœa, which soon ceased. On the fifteenth day there were severe tremors. Hæmorrhage was predicted, and turpentine and opium mixture[2] ordered to be given as soon as bleeding occurred. On the seventeenth day blood came in gushes from the bowel, and during the next twenty-four hours several pints must have come away. The patient's condition became very low, but he eventually made a good recovery in spite of the fact that on the thirty-sixth day an immense bedsore formed which exposed nearly the whole of the sacrum.

Headache and delirium.—Headache is nearly always present during the first half or the first third of the disease, and disappears spontaneously. Hence, I have very rarely had occasion to direct any special treatment against it, owing to the fact that the headache period has nearly gone by before the patient has arrived in hospital.

I have not been able to verify the statement of Broadbent, in Quain's *Dictionary of Medicine*, that severe and persistent headache is the forerunner of intestinal hæmorrhage.

Delirium generally means danger, yet it is not necessarily a very unfavorable symptom. Fierce delirium was present in several instances, notably in that of a Hungarian, whose case is already recorded,[1] and who was at first thought to be suffering from acute mania. Delirium was a prominent symptom in 8 of the 84 non-fatal cases, and in 7 of the 16 fatal cases, and in 2 of the latter it was very furious.

Duration.—The duration of a fever can only be estimated by the number of days spent in hospital, and this depends upon the season of the year, the climate, and the character of the hospital. The average duration of non-fatal cases was 40.8 days. The longest case lasted 80 days. The shortest stay in hospital was 7 days. This last patient had been ill for some days before admission, and came from a house where there were three other cases of fever.

Retention of urine occurred in 7 of the 84 non-fatal cases, and in 4 of the 16 fatal cases, or in 11 per cent. of all cases. Incontinence of urine and fæces was noted as being urgent and troublesome in but 2 cases, neither of which was fatal.

Epistaxis was not serious in any case.

Venous thrombosis occurred in but 2 cases, both non-fatal.

Relapse.—It was a surprise to me to find the history of but one relapse, for I was under the impression that relapses were of much more common occurrence. Experiences upon this differ within very wide limits, owing to a diversity of opinion as to what constitutes a relapse. Thus, Murchison recorded 80 relapses in 2591 cases in the London Fever Hospital, or in 3 per cent.; Griesinger (quoted

[1] Boston Medical and Surgical Journal, vol. cxxi., No. 10.

[2] Tannic acid, 10 grains; tinct. of opium, 10 minims; spirits of turpentine, 15 minims; mucilage, 2 drachms; compound tinct. of chloroform, 20 minims; peppermint water, 1 ounce, every two hours. This formula is borrowed from Murchison's work on the Continued Fevers.

[1] Montreal Medical Journal, vol. xviii. p. 444.

by Murchison) in 6 per cent.: Human in 8 per cent.; Maclagan in 10 per cent.[1]

I accept Dr. Murchison's definition of a relapse as being "a second evolution of the specific febrile process, after convalescence from the first attack is fairly established," and a relapse includes such symptoms as rise of temperature, rigors, chilliness, headache, pains in limbs, loss of appetite, furred tongue, nausea and often retching, diarrhœa, enlarged spleen, and a fresh eruption of rose spots. The number of relapses would be much increased were we to take into account those cases in which the relapse began before the original disease terminated. On this point my cases have not been examined.

Recrudescences, or what are commonly called relapses, were not frequent, owing, I believe, to the rule carried out that no change in the diet was to be made until the patient had shown a normal night temperature for a week.

Perforation was found at the autopsy of one patient, but in the Montreal General Hospital the occurrence is more frequent than my figures would indicate. Dr. Wyatt Johnston, the present pathologist, tells me that in 18 autopsies since 1886 he has found perforative peritonitis in 3, and Dr. Osler, who was his predecessor in the same office, found it 11 times in 53 autopsies. These figures are much higher than are elsewhere given. Autopsies are very difficult to obtain in cases of fever. The friends cannot understand why, if the doctors are satisfied that fever was the cause of death, they should wish for further examination.

Pregnancy.—The one pregnant woman with typhoid fever died. Murchison reports 10 recoveries in 14 cases, and in 2 of the 10 recoveries the patients carried the child through the fever.

Strümpell, in his *Practice of Medicine*, makes the observation that when abortion occurs in the course of typhoid a marked fall of temperature takes place. In my case the result was different; the temperature ran steadily up after abortion, reaching 108° in twenty-four hours, when the patient died.

Syncope.—In three non-fatal cases severe syncopal attacks occurred. I have seen sudden fatal syncope occur in convalescence from typhoid fever.

Complication with other diseases.—The following complications were noted—all in non-fatal cases: whooping-cough, old thickening of one pleura, diseased mitral valve with cardiac hypertrophy, periostitis of the superior maxillary bone, multiple abscesses, parotitis, and acute anterior poliomyelitis. One patient was a "jumper" from a lumber camp in Maine. He "jumped" consistently all through the fever and convalescence.

[1] Murchison on the Continued Fevers. Third edition, London, p. 552.

Pulmonary tuberculosis after typhoid fever.—I have never seen phthisis occur after typhoid fever, but upon several occasions I have made the mistake of regarding cases of tuberculosis as being typhoid fever.[1]

In connection with this, Fagge says that "it is a remarkable circumstance that, after searching the records of post-mortem examinations at Guy's Hospital, I have failed to find a single case in point."

Mortality.—The recorded mortality of my 100 cases represents neither remarkably good nor remarkably bad success. It must be remembered that the average age was twenty-four years. The London Fever Hospital has an aggregate mortality of 17.61 per cent., but a large number of the deaths occurred in the young. The mortality of Homerton Fever Hospital is 17.83 per cent., and that of Stockwell Fever Hospital 22.90. Shattuck's mortality in the Massachusetts General Hospital is but 8.37 in 129 cases, but it must be remembered that that hospital is not like ours, which is a city, marine, and immigrant hospital combined. A certain not insignificant proportion of cases were brought to the hospital practically moribund.

1 patient	died	on the	3d	day	after admission.
1 "	"	"	5th	"	"
3 patients	"	"	6th	"	"
2 "	"	"	7th	"	"
1 patient	"	"	9th	"	"

Nearly all these had been transported from outlying villages.

I refuse to acknowledge the fairness of any comparison with figures taken from the experience of private practice. Medical men, unless they are most careful in noting cases, are apt to deceive themselves, and to think in a vague and uncertain way of their success or non-success, principally of the former. Private patients of the well-to-do classes have every possible point in their favor. They are not obliged to go on working as long as possible, and they are likely to meet with sensible treatment. Moreover, they have no transportation to undergo,—a very strong point in their favor. Only one-half of my fatal cases came from the city.

General treatment.—I have no faith whatever in the effect of medicines on the fever. Antiseptics are unpleasant to take, and in my opinion no more effective than so much water. To talk of disinfecting an abdomen full of typhoid excreta with small doses of carbolic or sulphurous acid seems to me as absurd as homœopathy.

Though all my patients have taken small doses of the mineral acids, I have prescribed these merely as a *placebo*, and I do not believe they have any action whatever.

[1] See Canadian Practitioner, June, 1888.

To purge at the outset, if constipation is present, is good practice, and I have frequently given 2 grains of calomel every two hours until the bowels moved. After that I follow Todd's advice, and when the bowels are fairly locked up I keep them so, merely ordering an injection every two or three days.

Diarrhœa itself seems to be dangerous, and no one can watch the course of many cases without being struck with the fact that it does not tend in any way to mitigate other symptoms whether abdominal or cerebral. Diarrhœa accompanies the worst cases of tympanites, and in hæmorrhagic cases it is often present.

Antipyretics.—Cold sponging was practised in all cases in which the temperature went above 102°. I have had no experience with the use of cold baths.

On the medicinal antipyretics I do not place any reliance. I remember well the days when no typhoid-fever patient could die without heavy doses of quinine. And where are they who now advocate quinine? A case in which temperature alone is killing the patient calls for antipyretics, but such cases are rare. Looking over my 16 fatal cases, I see that but 4 died with no other formidable symptom than high temperature. In Osler's 53 autopsies there were but 16 cases in which some such definite lesion as perforation, hæmorrhage, etc., was not present[1]—that is, but 16 cases on which antipyretics might have exerted a beneficial influence.

It would appear in some cases that, if we could overcome the hyperpyrexia, the patient would get well. Take, for example, the case of Matilda R.[2] This was a very severe case, and there were no symptoms beyond those which might have been attributed to the effects of heat. Now in this case there were found most extensive lesions in the bowel which were evidently keeping up the temperature. It seems to me that the use of antipyretics can have no better effect in typhoid fever than they would have in the fever of an internal abscess. In cases where other symptoms are bringing about the fatal result, symptoms such as extreme meteorism, exhausting diarrhœa, or severe brain symptoms, they are more than useless.

Some of the best recoveries from hyperpyrexia have taken place in cases in which no antipyretic was given. As, for example, the following case:[3]

A sailor who on the tenth day showed a temperature of 105.6° at 8 P. M., reaching 106° at 5.30 in the early morning of the twelfth day and dropping suddenly to 99° before 8 A. M.—a fact which shows the necessity of taking the temperature during the night as well in the morning and evening. The next rise, to 105.5°, took place in the afternoon of the same day, the temperature falling to 101.8° before 8 P. M. The highest point was reached, however, on the thirteenth day, when, at 2 A. M., it was 107°, but, as on the preceding day, a drop to 99° occurred, and the patient gradually recovered. This case occurred in 1884, and I have only to repeat what I said then, that I have lost faith in medicinal antipyretics.

We have come to regard confidently a morning fall and an evening rise as of regular occurrence —*e. g.*, in a private patient we have the temperature taken at 8 P. M., and if it be normal then we assume that it has been normal for the preceding twenty-four hours. This is a great mistake. If the temperature is taken hourly it will be found to vary greatly. In the case already described, as an instance of genuine relapse, the temperature was found very high when registered every four hours; being higher in the early part of the afternoon than in the evening, so that had we depended merely upon observations at 8 A. M. and 8 P. M. it would have entirely escaped our notice that hyperpyrexia was present. The truth is that remissions and exacerbations take place at any period in the twenty-four hours. "Generally the minimum temperatures occur between midnight and noon, and the maximum between noon and midnight."—*Colley.*

And in this way we deceive ourselves in the matter of antipyretics. For example, the case is running smoothly until we find that the temperature at 8 P. M. is too high; we accordingly give, say antipyrine, and then, and not until then, we begin making observations every four hours. Consequently it is just possible that our observation after 8 P. M. may show a fall which we hasten to ascribe to the effect of our medicine.

I have found antifebrin more satisfactory than antipyrine. It has been given in 3-grain doses every three hours.

CEPHALHÆMATOMA.

A Case of Sub-pericranial Blood-tumor in the Newborn Child.

BY HOWARD A. KELLY, M.D.,

GYNECOLOGIST AND OBSTETRICIAN TO THE JOHNS HOPKINS HOSPITAL, BALTIMORE.

My desire in reporting a case of this interesting disease is not so much to place on record another example of a rare affection, but rather to call the attention of the profession to one of the most important, and as yet but rarely recognized diseases of very early childhood, as well as to prepare the way for a discussion of this subject at the meeting of the American Gynecological Society, to be held on September 16th of this year. Few men outside of the ranks of the pure specialists are aware that such a disease as cephalhæmatoma (cephalohæmatoma)

exists. Cases which occur in the practice of the general practitioner are diagnosed and treated by him upon "general principles."

The information which he possesses upon this subject is fairly comparable to that of a physician practising early in the last century.

A well-defined disease appearing soon after birth, running a brief, definite course, tending, as a rule, to resolution, but capable of seriously affecting the health, or even of implicating the life of the child, must be a matter of interest to every medical man; and the interest is heightened by the relative frequency of the disease (probably one in 250 obstetric cases), with the certainty that even a moderate obstetrical experience will sometime surely bring one or more cases under observation, and demand decision as to their nature and the course to be pursued.

Our curiosity is still further aroused, and our interest enhanced, when we learn that we have here also one of those curious examples of the tendency, felt even in scientific matters, of an important discovery to remain for a long time in the almost exclusive possession of its original promulgators, while, in the face of the clearest demonstrations and the most numerous writings, surrounding nations long seem to ignore its existence.

Thus the discovery of cephalhæmatoma dates from the close of the last century, when Dr. Michaelis, of Harburg, wrote in the second volume of *Loder's Journal*, "upon a peculiar kind of blood tumor,"[1] giving a full, clear account of the affection. This able article provoked within the succeeding thirty years a host of other writings, and abundant records of cases, in various German journals, and since that time cephalhæmatoma has been regularly registered among the more important diseases to which the newborn are liable.

In the following brief description of the disease, before illustrating my subject with the report of a case, I will make free use of the language of Michaelis.

Cephalhæmatoma (the name given to the disease by Naegele[2]) is a circumscribed effusion of blood between the periosteum and one of the flat cranial bones, appearing usually the day after birth, and gradually increasing in size until it forms a tense, prominent, rounded, or ovoid swelling. Its commonest seat is over one or both parietal bones. It is always lateral, never crossing a suture. The skin over the tumor remains movable and unaltered in appearance. The tumor is not painful, and does not decrease in size upon pressure. After two or three weeks, as a rule, it gradually disappears by absorption.

One of the most important diagnostic signs of the disease is the existence of a bony wall, one or two millimetres in height, which surrounds the whole outer circumference of the tumor. This can be distinctly felt through the skin, and gives at once the impression of a depressed fracture.

Injury usually has no apparent connection with the origin of this tumor, which often appears after natural, easy, and short labors, and upon a part of the head which was not prominent in the birth. Instead of being absorbed the collection of blood may undergo suppuration, perforating the cranial cavity, or rupturing externally.

The earlier observers frequently incised the tumor, cleaned out the blood, and put on a compress. The best treatment to-day is to wait for two or three weeks for resolution by absorption, and, if this should not take place, to incise and empty the sac under strict antiseptic precautions, and apply an antiseptic dressing. Whenever signs of suppuration arise the tumor should be freely opened at once, well washed out, and drained.

This, in brief, is the outline of the disease to which I desire to call attention by this preliminary note, in advance of a more formal, elaborate article upon the same subject, prepared for the meeting of the American Gynecological Society. The following case recently came under my observation:

I was called early one morning last June to attend Mrs. A., primipara, forty-one years old. She was of medium height, had a normal pelvis, and the uterus contained a living child.

She had had pains with great regularity during the preceding night, with the effect of bringing the head well into the pelvis, with the occiput to the left and anterior. The waters had already discharged through the os, which was dilated to about 2 centimetres. By noon the strong, regular pains had brought the head to within an inch of the floor of the pelvis—well flexed, and the flat bones extensively overlapping. At this point the head became firmly wedged. From 1.38 to 7.25 o'clock in the evening she had 106 pains, without bringing the head a half inch nearer the pelvic floor. The child was in good condition, but the mother seemed so exhausted that I then gave her benumbing doses of chloroform by inhalation, and applied Naegele's forceps. By assisting each pain I delivered her after an hour, with a slight tear, entirely within the vagina and in the left sulcus. The child was a female, weighing about 3000 grammes. At the outer angle of its right eye was a slight indentation in the skin from the pressure of the forceps, which disappeared in two days.

A large caput succedaneum covered the occipital region. No other deformity or evidence of injury was visible. On the second day I observed a reniform swelling over the most prominent portion of the right parietal bone, 6 cm. in length by 2.5 in breadth, lying entirely within the border of the

[1] "Ueber eine eigene art von Blutgeschwülsten."

[2] V. Zeller: De Cepha'hæmatomate seu sanguineo cranii tumore recensnatorum. Heidelberg, 1822.

bone, which could be felt on all sides around the swelling. The concavity of its circumference looked downward toward the right ear, while its convexity was more or less parallel with the sagittal suture.

Showing the position of the cephalhæmatoma. Its relative size is greater than natural. The dotted triangles represent the bony plates which formed in the pericranium as the tumor disappeared.

At first slightly elevated, the tumor distended in two or three days, until it formed a prominent, rounded, tense sac. Its circumference did not appear to increase. Elasticity and fluctuation were distinct. There was no pulsation.

Pressure was painful only upon being prolonged when the child became restless. It did not reduce the size of the tumor. The scalp over the tumor was movable and unchanged in appearance. Surrounding the whole margin of the tumor a distinct sharp ridge could be felt, and within this craterous orifice palpation at first conveyed the sensation that the bone was wanting. Deeper palpation, however, touched the bony floor, removing the deception.

The tumor thus formed resembled in shape a potato cut in half lengthwise and laid flat on the head. It thus made a very conspicuous deformity, giving the head an extraordinary lop-sided appearance. The treatment was a policy of inactivity.

I did absolutely nothing to the tumor. In about ten days it began to diminish in size, and in three weeks and a half it had almost entirely disappeared. At this time there was still a slight elevation, and on pressure the fluid seemed to shoot under a parchment-like membrane. The borders felt rough, and from the upper margin two triangular plates projected over the denuded bone, apparently lying in the periosteum. Later no trace of the tumor could be detected.

THE TOXIC PRODUCTS OF THE BACILLUS OF HOG-CHOLERA.

BY FREDERICK G. NOVY, Sc.D.,
INSTRUCTOR IN HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN, ANN ARBOR.

THE fundamental researches of Löffler, Schütz, Lydtin, and Schottelius, in Europe, and of Salmon and Smith, in America, have demonstrated the existence among swine of at least three distinct infectious diseases. These are:

1. Hog-erysipelas, or *rouget* of France, and *schweinerothlauf* of Germany.
2. Swine-plague, or *schweineseuche.*
3. Hog-cholera, or *schweinepest.*

The first of these, hog-erysipelas, is exclusively a European disease, and has not, so far as known, been observed in this country. In the course of this disease only general symptoms of infection, as in anthrax or septicæmia, are manifested. The most important anatomical changes are as follows: The spleen is markedly swollen and dark-colored; the mucous membrane of the stomach and intestines is inflamed and infiltrated with blood; a parenchymatous inflammation of the liver, heart, and muscles is present, as well as some reddening of the skin.

The second disease, swine-plague, appears to be common to both continents. It may be characterized as an inflammation of the lungs and skin, accompanied with death of the lung tissue and slight symptoms of infection. When the disease becomes chronic, a caseous condition of the lungs results which may excite a similar condition in the lymphatic glands and the joints.

The third, hog-cholera, is preëminently a disease of the digestive tract, and the large intestine is especially involved. It is the great swine-disease of this country, and is very probably present in England associated with other forms of disease under the name of swine-fever. On the European Continent this disease was unknown until 1887, when it suddenly appeared in France, Sweden, and Denmark.

Apart from this sudden visitation of hog-cholera in the above-mentioned countries of Europe, it may be said that on the Continent there are two prevalent diseases—hog-erysipelas and swine-plague. In this country the former is entirely absent, and appears to be replaced by hog-cholera, so that the two swine-diseases in America are hog-cholera and swine-plague.

A very careful bacteriological study of these three diseases has shown their microbic origin. The researches of Löffler demonstrated the etiological importance of the bacillus of hog-erysipelas; those of Schütz accomplished the same with reference to the bacillus of swine plague; and lastly, Salmon and Smith have demonstrated that hog-cholera owes its origin to a specific bacillus.

But even when the causal relation of a germ to a disease has been shown, it does not follow that all the problems connected with the production of the disease have been settled. Rather the reverse. The first question that then arises is: "How does the germ produce the disease?" To answer this question briefly, without taking up discarded theories of only historical importance, consider the growth of the simple yeast-cell, an organism closely related to the bacteria proper. The saccharine solution in which the yeast-cell is grown may produce, when

ingested, marked toxic symptoms—*i. e.*, intoxication. The effects are not due, as is well known, to the yeast-plant directly, but to the chemical products formed by its growth—in this case, to the alcohol. And such is the explanation of the manner in which bacteria produce disease. In the body, whether of man or animal, these small disease-producing microorganisms find all the material necessary to their growth and multiplication. Like all living beings, they consume material which enables them to grow and multiply, and at the same time they secrete or give off products of cell-metabolism which may or may not be injurious—*i. e.*, toxic. Analytic as well as synthetic changes are constantly carried on during the lifetime of the simple bacterial cell, corresponding thus in every respect to the more highly organized members of the vegetable and animal kingdoms.

Among the products resulting from the growth of these microörganisms none have received more attention up to the present day than those which are known under the generic name of ptomaïnes. The word ptomaïne, first applied by Selmi to designate the basic or alkaloidal compounds which he found in decomposing cadavers, has been enlarged in its significance so as to embrace all basic products formed by bacteria in general. We, therefore, may have ptomaïnes produced by the activity not only of disease-producing bacteria, but also by the engenderers of putrefaction. With respect to their physiological action, it is customary to speak of toxic and non-toxic ptomaïnes. Quite recently, however, Brieger, of Berlin, who has done more than anyone else to bring light into this heretofore obscure field of knowledge, has proposed to restrict the word ptomaïne to only the non-poisonous basic products generated by the activity of bacteria, and to designate the poisonous basic bacterial products by a corresponding generic term, *toxine*. It is unnecessary at this point to consider the merits or faults of this classification, and beyond the mere statement of the fact it will receive no further attention. The term ptomaïne has at present such a well-accepted significance that it seems undesirable to restrict its meaning, and for that reason it is retained in this paper in its original sense.

In the light of very recent investigations, however, it seems that the noxious functions of bacteria can be manifested in the production of toxic bodies other than ptomaïnes. The latter may be considered as the final products of the action of bacteria on the proteid molecule; but intermediate between the complex harmless proteid and simple but toxic ptomaïne we may have one or more cleavage-products closely related to and apparently undistinguishable from the parent proteid molecule, except in physiological action. These new poisonous products generated by bacteria have been designated as *toxalbumins* by Brieger and Fränkel.

A brief *résumé* of the work of these two investigators will not be out of place at this point. Its great importance from a chemical standpoint, and the influence that it will undoubtedly exercise in the future, bringing forth as it does a great, if not the greatest, etiological factor in microbic diseases, will be readily recognized.

In studying the poisonous products generated by the growth of Löffler's diphtheria bacillus, Brieger and Fränkel found that the culture, liquid-freed from its bacteria by filtration, possessed a high degree of toxicity, which was partially lost when the liquid was kept at 60° C. for a short time, and completely destroyed by an exposure of ten minutes to a temperature of 100°. It could, however, be evaporated at 50°, or less, even when acidulated with hydrochloric acid. This showed that the poisonous substance was readily decomposed by a temperature exceeding 60°. A careful examination for basic products yielded absolutely negative results. The poisonous principle was found to be insoluble in absolute alcohol, but soluble in water, and thus could be obtained in a condition of purity. Its reaction showed it to be related to the serum-albumins, while chemical analysis indicated relationship with the albumoses or peptones. Even in very small quantities it causes in rabbits fatal results, which may not supervene until after an extraordinarily long time—weeks, and even a month.

From cultures of the same bacillus, after it had lost its virulence, a similar proteid body was obtained, which, however, was wholly inactive. Cultures of the bacillus of typhoid fever, of the bacillus of cholera, and of the staphylococcus pyogenes aureus yielded toxic globulin-like bodies; whereas, those of the tetanus and anthrax bacilli give toxic albumin-like bodies, resembling that obtained from diphtheria cultures.

Independently of Brieger and Fränkel, and at about the same time, Baginski and Stadthagen found that cultures of a common saprogenic intestinal bacillus, similar to, if not identical with Finkler-Prior's bacillus, produced, in addition to a moderately poisonous base, a toxic proteid substance related to the peptones.

The existence of poisonous proteid bodies formed by the growth of microörganisms, was shown by Christmas and by Hankin, some time previously to the investigations just referred to. From cultures of the staphylococcus pyogenes aureus, Christmas (1888) isolated a proteid substance which, when introduced into the anterior chamber of the eye, or into the subcutaneous tissue, produced suppuration. Hankin, in 1889, obtained immunity in mice and guinea-pigs against anthrax by first inoculating the

animals with an albumose-like body, which he obtained from cultures of the anthrax bacillus.

In the following pages the results obtained from a study of Salmon's bacillus of hog-cholera will be given. The work at first was made to cover a search for the ptomaïnes generated by this microörganism, but subsequently has included an examination for toxalbumins. The methods pursued in this investigation were in general an adaptation of the methods of Brieger. The culture of the microörganism employed was obtained from the Agricultural Department at Washington, and before use was passed through a number of rabbits in order to secure maximum virulence.

Methods and results of analysis.—As a culture-medium pork broth was employed, and was prepared as follows: The finely-hashed pork was treated with distilled water, in the proportion of one litre of water to 500 grammes of meat. The mixture was then placed in tin pails, and heated in a steam sterilizer two hours daily for several successive days, in order to remove the excess of fat. This done, the material was poured into a number of half-litre and litre flasks, which had been previously cleaned, closed with a tight-fitting plug of cotton, and efficiently sterilized by heating for two or three hours at about 175°. The flasks, thus equipped, were sterilized in a Koch's steam-sterilizing apparatus by heating, two hours each day, for three consecutive days. When cool the contents were inoculated with the above-mentioned virulent culture of the hog-cholera bacillus, and the flasks then set aside in incubators, at a temperature of 35–37° C., where they remained nearly eight weeks.

At the expiration of that time the flasks were taken out and the contents subjected to examination. They were found to possess a strong alkaline reaction and an amine odor. A portion when heated on a water-bath gave off alkaline vapors, and the odor was more marked. Only those flasks were reserved for further study which were found to contain pure cultures of the hog-cholera bacillus.

Several preliminary examinations were made to ascertain the presence or absence of phenol, indol, and related bodies. For this purpose about 100 c. c. of the clear culture-liquid were acidulated with sulphuric acid, a marked effervescence resulting, and then subjected to distillation. A number of such distillations were made, but at no time was any reaction obtained on addition to the distillate of bromine water, or of hydrochloric or nitric acid, showing the entire absence of phenol, skatol, and indol.

The remaining contents of the flasks were then acidulated with hydrochloric acid and filtered through muslin. The filtrate, amounting to about six and a half litres, was neutralized with sodium carbonate solution, and evaporated on a water-bath. The residue of meat-fibre was extracted with about three and a half litres of five-per-cent. hydrochloric acid solution, filtered, and the filtrate evaporated separately, taking care, as before, to keep the liquid neutral.

In both cases thick, syrupy residues were obtained, which were taken up with successive portions of absolute alcohol, the extraction being markedly facilitated by the use of a pestle, whereby the material was reduced to a fine granular condition. The alcoholic solutions thus obtained were then combined and filtered, and the clear solution was precipitated with an alcoholic solution of mercuric chloride. An abundant, white, amorphous precipitate was obtained. This was filtered off, washed with absolute alcohol, then suspended in distilled water, and decomposed by a current of hydrogen sulphide. After removing the sulphide of mercury by filtration the filtrate was concentrated, taking care to keep the liquid near the neutral point, and finally again treated with hydrogen sulphide to remove the last traces of mercury.

The filtrate, now perfectly free from mercury, was neutralized and evaporated to dryness on a water-bath. A yellowish-brown syrup, containing some needle-shaped crystals and some crystals of salt, was obtained. This was taken up in 100 c. c. of distilled water, neutralized, and small quantities were injected into rats. One-fourth c. c. produced death in a very short time, preceded by spasmodic contraction of the limbs. The animal died on its side, with the feet extended. One-eighth c. c. produced marked excitement at first, but subsequently the animal assumed a fixed position, and the eyes were half-closed by a thick secretion. It was found dead thirty-six hours later, lying on its side, with the feet extended. Post-mortem examination showed bright-red lungs; heart in diastole: liver dotted with minute hæmorrhagic spots; spleen very light in color; kidneys mottled with superficial necrotic spots: and intestines reddened along the entire length, and with swollen, inflated patches.

These experiments demonstrated that a substance of marked toxic properties was present in the residue from the mercuric chloride precipitate. The solution was again evaporated to dryness on a water-bath, and the residue again extracted with a considerable amount of absolute alcohol. The alcoholic solution was in turn precipitated with alcoholic platinic chloride. A rather large flesh-colored precipitate was obtained, which was transferred to a filter and washed well with absolute alcohol.

The filtrate from the platinic chloride precipitate was diluted with water, and decomposed with hydrogen sulphide, and the filtrate thus obtained gave a

small quantity of a sticky syrup, apparently identical with the syrupy salt obtained from the platinum precipitate. It may be mentioned at this point that the mercuric chloride filtrate was decomposed in like manner. It gave a considerable amount of ammonia, but otherwise no toxic substance was present.

The platinum chloride precipitate was then treated with cold distilled water, which readily dissolved all but a very small portion. The solution was filtered off, and the filtrate on standing gave a yellow deposit of a platinum compound, which under the microscope appeared perfectly homogeneous, and in the form of clear, yellow, oil-like globules. This deposit was filtered off, well washed with water, then dried at 75°C. The filtrate, on standing forty-eight hours, gave a second deposit, which was likewise removed by filtration, washed and dried as before. This deposit was subjected to elementary analysis, and the results obtained were tabulated (Table I.). The

Table I.

	Per cent. found.		Average.	Calculated per cent. for $C_8H_{14}N_4PtO_8$.

N =	11.65	.....	11.65	11.47
Pt =	39.64	39.90	39.77	39.80
O =	.....	.....	.....	26.20

addition of alcohol to the solution of the platinum precipitate, after removal of the last deposit, gave a light-yellow granular precipitate, which was found to consist almost entirely of the same compound as before. The alcoholic filtrate from the original platinum chloride precipitate, on standing some days, likewise gave a deposit of the same characteristic bright-yellow oil-like globules, which were likewise separated by filtration, well washed with water, then dried at 75°, and analyzed. The substance was not found to contain chlorine or sulphur. The results obtained are given in Table II.

In the dry condition this compound, which, perhaps, is closely related to creatin, forms a dull-yellow powder. When completely dry, it is insoluble in hot and in cold water; soluble in acids and alkalies, from which solutions it gives precipitates with barium chloride and silver nitrate. Owing to the small quantity at my disposal it was not possible to free the substance from platinum.

The dilute alcoholic filtrate from which the preceding compound was obtained was found to contain a platinum salt, crystallizing in long needles. In order to isolate this substance the filtrate was diluted with water, and the platinum removed by hydrogen sulphide. The filtrate from the platinum precipitate was concentrated on a water-bath, taking care to keep the solution near the neutral point. The small amount of platinum which was still in solution, and had not been precipitated before owing to the presence of free acid, was now entirely removed, and the neutralized solution free from platinum was evaporated to dryness, or, rather, to a thick, dark-yellow syrup. The residue was taken up in distilled water, and decolored as much as possible with animal charcoal. The light-yellow solution thus obtained was again evaporated to dryness, and, in order to remove the salt, the residue was extracted with cold absolute alcohol, in which the syrupy portion was found to dissolve quite readily. The alcoholic solution in turn was evaporated to dryness, the light-yellow syrup again taken up with cold absolute alcohol, and this operation repeated until all the salt was removed.

In this manner a light-yellow syrup was finally obtained, which showed no tendency to crystallize, even when kept for a week at a temperature of 37°. It was soluble in water and alcohol, and proved to be the hydrochloride of a new base. In order to prepare it in a form suitable for analysis it was taken up in cold absolute alcohol, and the clear solution precipitated by an alcoholic solution of platinum chloride. The finely granular, light flesh-colored precipitate thus obtained was thoroughly washed with alcohol, dissolved in a small quantity of water, filtered, and from the filtrate the platinum salt was again precipitated by the addition of absolute alcohol. This precipitate was transferred to a filter, well washed with alcohol, and finally dried at 75°. On elementary analysis it gave the following percentage composition: C=20.40, H=4.67, N=4.99. These figures agree very closely with the calculated percentages in the formula $C_{10}H_{26}N_2.2HCl.PtCl_4$, in which C=20.57, H=4.79, N=4.79. The per cent. of platinum in the substance, however, varied in the several determinations, and from the theoretical value, so that it will be necessary to re-determine the composition of this new base as soon as new material is obtained.

The free base appears, therefore, to be a diamine, and future examination will prove whether it posseses the formula $C_{10}H_{26}N_2$. It exhibits marked, though not very strong, toxic properties, as will be seen from the experiments to be described. Moreover, it appears to be the only basic compound present which possesses such properties. On this account it is named, temporarily, *susotoxine*, from the Latin *sus*, a hog. The quantity obtained did not suffice for the isolation and study of the free base, and such examinations as were made were, therefore, confined to the hydrochloride.

The hydrochloride was obtained by decomposition of the platinum salt as a light-yellow, perfectly clear syrup, which showed no tendency to crystallize or harden, either on standing at the ordinary temperature or when kept for a week in the incubator at 35°. It is somewhat hygroscopic, and is readily

soluble in water, as well as in cold absolute alcohol. When heated with a fixed alkali it gives off a strong amine odor, such as is perceived on evaporating the original culture fluid, if it happens to be alkaline in reaction. The following table gives a synopsis of its reactions with reference to the common alkaloidal and other reagents:

TABLE II.

	Alcoholic solution.	Aqueous solution.
Alc. $HgCl_2$	Heavy, white precipitate, soluble in water.	Slight cloudiness.
Alc. $PtCl_4$	Whitish precipitate, soluble in water.	Addition of alcohol produces precipitate.
Alc. $AuCl_3$	Slight cloudiness.	" " " "
Alc. picric acid . .		
Phosphotungstic acid	Heavy, white precipitate.	Heavy, white precipitate, soluble in NH_4OH.
Phosphomolybdic acid	Heavy, yellowish precipitate.	Heavy, yellowish precipitate, soluble in NH_4OH, producing faint blue color.
Sodium tungstate . .	Flocculent precipitate.	" " " "
$I + KI$	Addition of water produces precipitate.	Dirty-brown precipitate.
Bromine water . .	Addition of water produces precipitate.	Abundant yellow precipitate.
NH_4OH		" " " "
$(NH_4)_2CO_3$		" " " "
NH_4CyS	.....	Slight cloudiness.
KOH	Amine odor on heating.	Volatile amine on heating.
Fe_2Cl_6		" " " "
$AgNO_3 + NH_4OH$.		" " " "
Tannic acid . . .	.....	Heavy, flocculent, yellowish-white precipitate.
Lead acetate . . .		" " " "
Copper acetate . .		" " " "

The platinochloride is obtained by precipitation as a light, flesh-colored, granular precipitate. It is readily soluble in water, from which it can be reprecipitated by addition of absolute alcohol. From aqueous solution, when allowed to evaporate slowly, it crystallizes in long, thick needles.

The mercurochloride is thrown down from solutions of the hydrochloride in absolute alcohol, by alcoholic mercuric chloride, as a heavy, white, granular precipitate. This readily dissolves on the addition of a small quantity of water, and can be perfectly reprecipitated by addition of absolute alcohol. On treatment with hydrogen sulphide it is readily decomposed, yielding the pure hydrochloride.

The aurochloride is very soluble in water and alcohol. From the alcoholic solution it may be partially precipitated by ether as a light-yellow, oily precipitate, which is adherent to the sides and bottom of the tube.

Physiological experiments.—By a series of preliminary experiments made with sterilized culture-fluid on animals, it was shown that a relatively large amount was necessary to cause fatal results in rats. Thus, 50 c. c. of the culture-fluid of the hog-cholera bacillus were sterilized by heating one hour at 60°, then acidulated with hydrochloric acid, and concentrated at a low temperature on a water-bath to 6 c. c. Of this, 3 c. c., representing 25 c. c. of the original culture-fluid, were neutralized and injected subcutaneously into a young white rat. At first the animal was quite uneasy and jumped about, and the respiration became rapid; but it soon became quiet, the head most of the time resting, and the eyes closed. In about half an hour the gait became staggering, and a sleepy condition, with unwillingness to move, prevailed. About four hours later the animal became comatose, lying with the head horizontal, the respirations were slow and deep, and it finally died in this position. Post-mortem examination showed some bloody infiltration under the skin; a jelly-like mass at the seat of inoculation; the heart in diastole; lungs bright-red; some exudate in the pleural cavity; liver soft, but otherwise normal in color and size; kidneys and spleen normal.

The general course of the symptoms thus observed corresponded exactly to those obtained by inoculating rats with unsterilized cultures, except that in the latter case, where the disease lasted several days, a thick secretion formed between the eyelids and the animal passed abundant soft fæces.

In another experiment the clear culture-fluid, after being sterilized by heating to 60° for one hour, was evaporated on a water-bath, without neutralization with an acid, to dryness. The residue was taken up in a little water, and a portion of this solution, corresponding to 15 c. c. of the original culture-fluid, was injected subcutaneously into a young rat. The animal remained in a perfectly quiet condition for some hours, with, perhaps, slightly increased respiration. Its hind legs soon appeared to be affected, for the animal sat upright with difficulty, and showed a tendency to topple over; the eyes were closed: ears pale. About four hours later it recovered somewhat, and was able to crawl about, though it had but partial control over its hind legs. Eight hours after the inoculation the animal seemed to have recovered, but the next morning was found in a very depressed condition, lying perfectly quiet, with the eyelids closed, and conjunctivæ filled with a thick secretion. It remained in this condition during the entire morning, but about 1 P. M. toppled over on its side, and was unable to rise, though kicking vigorously. Finally, after some time, it regained an upright position, remained thus all the afternoon, and died during the evening. The post-mortem examination corresponded to that described above.

This experiment showed that the sterilized culture-fluid retained its toxicity, when evaporated, without neutralization, to dryness. When smaller quantities of the liquid were employed for injection the animals survived. The equivalent of at least 15 c. c. had to be injected in order to produce fatal results.

To test the physiological action of the syrupy hydrochloride, the following experiments were made: About 100 mg., dissolved in a little water, were injected subcutaneously into a young rat. The animal was at first quiet, apparently unwilling to move. After some ineffectual attempts at jumping it settled down in a recumbent position, and when placed on its side was unable to rise. Respiration was at first retarded, later increased, but toward the end was again very slow. Convulsive tremors shook the body at frequent intervals. The animal kicked vigorously. Reflexes were present almost to the end. As death approached, the red eyes whitened and took on a glazed, opaque appearance. Death resulted in one and a half hours. The animal was on its side, the feet extended. Post-mortem examination showed the heart arrested in diastole, lungs rather pale, stomach contracted, serum in thoracic cavity, subcuta pale and œdematous.

A second animal was given half of the preceding dose. It appeared very much affected in the course of the following hour, moving with difficulty; the next morning it was found with eyes closed, in a sleepy condition, and very unwilling to move. Forty-eight hours later this animal was given a second dose, the same in quantity as the first. This injection was borne without any apparent manifestation. Accordingly, the idea to make a third inoculation suggested itself, this time with the virulent pure culture of the bacillus, in order to see what degree of immunity, if any, had been secured. The animal was, therefore, inoculated subcutaneously with 1.5 c. c. of the bouillon-culture of the bacillus. As a control, two animals, from the same litter as the preceding, were selected, and were given by injection 1 and 2 c. c. of the same culture, respectively. Both controls died the next day, whereas the test-animal did not show any signs of indisposition for more than twenty-four hours after the death of the controls. On the third day a moist secretion appeared about the eyes, and the animal became unwilling to move, but ate well. This condition continued during the fourth day, and the animal finally died on the morning of the fifth day, more than three days after the death of the control-animals.

This experiment would, indeed, seem to indicate that a partial immunity had been conferred upon the animal by the injection of a pure ptomaïne. It would have been very desirable to repeat it upon a series of animals; but, unfortunately, the material was not abundant, and it was thought best to reserve the remainder for purpose of analysis. Whatever may be the significance of this last experiment, it is evident that the new base is decidedly toxic in action.

Toxalbumins of hog-cholera.—The researches of Brieger and Fränkel, Baginski, Stadthagen, Hankin, and Christmas, already referred to, suggested the desirability of examining cultures of the hog-cholera bacillus, with reference to the presence or absence of these new toxic substances.

For this purpose some pork-bouillon which had been inoculated with the bacillus of hog-cholera, was kept at 35-37° for a period of five and a half weeks. About 600 c. c. of the clear, filtered liquid were concentrated in vacuo at 36° to less than one-fourth its volume. The concentrated aqueous solution thus obtained was added, drop by drop, with constant stirring, to six or eight times its volume of absolute alcohol. The flocculent precipitate which formed was allowed to subside, then received upon a filter, and well washed with absolute alcohol. The filter was then spread open, and allowed to dry at the temperature of the room. There was thus obtained a light, dry, whitish, crumbling powder, which is readily soluble in water, yielding a slightly opalescent solution.

To test its action upon the lower animals, 100, 50, and 25 mg., respectively, were injected into three young rats, from one litter. The animal which received 100 mg. shortly afterward began to crawl vigorously around the side of the cage, on its belly, unable to rise. The eyes were soon flooded with a thick secretion, and its toes became red. Finally, it became quiet, lying on its belly, with the feet extended. The respiration became deeper, and a coma-like condition set in. The animal died, without struggles or convulsions, in about three hours. The animal which received 50 mg. went through the same course of symptoms, though to a less degree. It died under exactly the same conditions four hours after the injection. The animal that received 25 mg. became very sick, but finally recovered. The eyes were covered with a thick secretion, the toes were red, and the animal showed no disposition to eat or move. It passed a large quantity of soft fæces. This condition lasted about two days, and on the third it disappeared.

As a control to the preceding experiments, as well as to test the virulence of the liquid which had been concentrated in vacuo, a young rat, belonging to the same litter as the preceding, was given 3 c. c. of the concentrated liquid. The animal passed through exactly the same symptoms as those observed in the rat which had been given 25 mg., and finally died two days later.

One week later the rat which survived the injection of 25 mg. was given a second dose of 30 mg.,

with scarcely any effect following. Inasmuch as this indicated the establishment of a tolerance for the poison, it was decided to continue the injections at intervals with successively increasing quantities, and then, if the animal survived the maximum dose of the poison, to inoculate finally with a culture of the virulent germ, and thus obtain immunity to the disease. This expectation was realized. The animal was given, subcutaneously, at intervals of five, three, five, two, and four days, respectively, 40, 50, 75, 100, and 125 mg., without any effects. Control-animals inoculated with 100 and 125 mg. invariably died in from three to six hours. Three days after the last injection of 125 mg. the experimental animal was inoculated with 1 c. c. of a bouillon-culture of the highly-virulent germ. Only a slight temporary effect was observed during the first day, after which the animal recovered its former activity and appetite, and has remained in good condition ever since. A control-animal, which was given the same quantity of the same culture, sickened on the next day, refused to eat or drink, rested most of the time in a perfectly motionless condition, and finally died one week later.

From this experiment it will be seen that complete immunity can be produced in rats against the action of the bacillus of hog-cholera by previously introducing into the animal successively increasing doses of the toxalbumin generated by this microörganism.

A further study of this interesting toxic proteid is now being made, and the results obtained will be published in due time. It may be stated now, however, that the toxic properties of the substance are not destroyed when the dry powder is heated for one hour at 72°, but are effectually destroyed by heating for the same length of time at 100°.

To summarize the results which have been obtained from the study of the chemical products of the bacillus of hog-cholera, we may say that when grown in proper nutrient material it forms:

1st. A basic toxic substance, or ptomaine—*susotoxine*.

2d. A toxic proteid substance, or toxalbumin.

3d. That this toxalbumin is capable of producing immunity in rats against the action of virulent bacillus.

In conclusion, I desire to express my thanks to my friend Mr. Charles J. Greenstreet, who kindly executed the elementary analysis in this work.

A PRELIMINARY STUDY OF THE PTOMAINES FROM THE CULTURE-LIQUIDS OF THE HOG-CHOLERA GERM.[1]

BY E. A. V. SCHWEINITZ, PH.D.,
CHEMICAL LABORATORY, BUREAU OF ANIMAL INDUSTRY, WASHINGTON, D. C.

DRS. SALMON and SMITH, of the Bureau of Animal Industry, U. S. Department of Agriculture, were the first to demonstrate that the substances produced by bacteria in their growth in culture-media could be used for purposes of preventive inoculation. This they proved by a number of experiments upon pigeons, in 1887. They succeeded in producing immunity from hog-cholera by inoculating pigeons with sterilized culture-liquids of the hog-cholera germ. With a view to learn more of the products of these and other disease-germs, a chemical laboratory was recently attached to the Bureau of Animal Industry, and for a short time I have been engaged in studying the products in the culture-liquids of the hog-cholera germ. The bacteriological work was done by Dr. Moore, of the Bureau of Animal Industry. The advice of Drs. Salmon and Smith has also been very valuable, and it was at their suggestion that the work was undertaken. Although the experiments are not complete, we think it best to make now a preliminary statement in regard to some of the results obtained, reserving for the near future a more extended account of the work.

The researches of Brieger, Baginsky, Salkowski, Selmi, and others, have shown that the multiplication of a number of different bacilli produces basic substances of an alkaloidal character, called *Ptomaines*. Some of these bodies are very poisonous, and a number of them have been shown to be

[1] Read before the Chemical Section of the American Association for the Advancement of Science, August, 1890.

identical with certain of the artificially prepared amines. In general, the best results have been obtained by allowing the germs to multiply in beef-bouillon, and after a number of experiments we have found an acid bouillon containing 2 per cent. of peptone to be the most satisfactory medium for the growth of the hog-cholera germ. Erlenmeyer flasks of 500 c. c. capacity were used, the mouths of the sterilized flasks being closed with a cotton plug. After inoculating the liquid with the germ the flasks were allowed to stand in the incubator for from two to three weeks, at a temperature of about 37° C. At the end of this time the liquid had become cloudy, and considerable precipitate, due to the growth of the germ, was found at the bottom of the flask and in suspension. The fluid had a decidedly alkaline reaction. Careful examination showed that the culture-liquid had not become contaminated with foreign germs.

In endeavoring to isolate the chemical products from these liquids, the methods, with some slight modifications, by which Brieger obtained such brilliant results, were followed.

The culture-liquid, after being acidified with dilute HCl, was evaporated on the water-bath. The residue was then extracted with 98-per-cent. alcohol, and the filtered solution treated with mercuric chloride. A heavy crystalline precipitate was formed which increased upon standing. After filtration this precipitate was treated with water, and decomposed with sulphuretted hydrogen, and the mercury sulphide removed by filtration. From the filtrate, after removal of the excess of H_2S and concentration, I was able to isolate cadaverine, and a primary amine which I have not yet identified. The filtrate from the mercuric chloride precipitate was freed from excess of mercury by sulphuretted hydrogen, and the mercury sulphide filtered off. The residue, after concentrating this filtrate, was extracted with absolute alcohol, the solution thus obtained showing the presence of a salt of an alkaloidal character. The reactions were as follows:

With phosphomolybdic acid—light-yellow precipitate.

With bismuth-potassium iodide—red needles.

With phosphotungstic acid—a white precipitate.

With potassium iodide and iodine—brown-red precipitate.

With platinum chloride—yellow crystalline precipitate.

With gold chloride—yellow-red crystalline precipitate.

The double salt obtained with $PtCl_4$ was submitted, after crystallization from 96-per-cent. alcohol, to a preliminary analysis, giving results which correspond to the formula $C_{14}H_{34}N_2PtCl_6$.

The free base I have not yet succeeded in obtaining in a pure form, and will not be ready to give this ptomaïne a name until more is learned of its constitution. The hydrochloride of this base is soluble in absolute alcohol, but I have obtained the salt only as a thick syrup, which so far will not crystallize over sulphuric acid in vacuo.

By treating the original culture-liquids of the hog-cholera germ with a large excess of absolute alcohol a white flocculent precipitate was obtained, a portion of which was soluble in water, and could again be precipitated by alcohol. By repeated treatment in this manner with water and alcohol a small quantity of an albuminoid body containing C, H, N, O, and S was finally obtained. This substance, which we will call albumose, when dried over sulphuric acid in vacuo, crystallized in white translucent plates. After drying, it was still soluble in water, though it dissolved with more difficulty. The water solution gave with $PtCl_4$ an almost insoluble precipitate, appearing under the microscope as needle-like crystals.

The toxic effects of this albuminoid body and of the ptomaïne were tested by subcutaneous inoculation of guinea-pigs. At the point of the inoculation with the albumose there was swelling and the formation of a hard lump, which disappeared after four or five days. There was also a rise in the temperature of the animal for a few days, but in other respects it seemed to suffer no inconvenience.

After subcutaneous injection of a small quantity (½ c. c. or about 0.005 gramme) of the neutral solution of the hydrochloride of the new base before referred to, a rise of temperature in the animals was noted for a few days, and also necrosis and slight ulceration at the point of inoculation, otherwise the animals appeared well. The salt of this base, as well as the albumose, are, therefore, not virulent poisons. It may be added that special attention was given to keeping the solutions sterile, by means of a Pasteur filter, and that the absence of germs was determined by making plate-cultures.

According to an article in the *Berliner klinische Wochenschrift*, March, 1890, Brieger and Fränkel have succeeded in isolating from culture-liquids (containing 10 per cent. of blood-serum) of the diphtheria, typhoid fever, and cholera-infantum germs, albuminoid bodies which they call tox-albumose, and which are very poisonous in small doses.

From culture-liquids of beef infusion with peptone and 2 per cent. of blood-serum, we have also obtained with the hog-cholera germ an albumose, having chemical properties similar to those described by Brieger, but not virulently poisonous to guinea-pigs when given subcutaneously, though there was considerable ulceration at the point of inoculation.

The detailed results of the experiments in pre-

ventive inoculation which have been conducted are not quite ready for publication. The statement may be made in advance, however, that by inoculating guinea-pigs with certain chemical compounds which I have prepared, the animals have been rendered immune from hog-cholera.

Having, therefore, made considerable progress in the study of the culture-liquids of this hog cholera germ, and also in preventive inoculation with chemical compounds, the results of this line of work are reserved for the present, and until more detailed results of the experiments can be given, which are promised for the near future.

COCAINE AND ANTIPYRINE COMBINED IN THE TREATMENT OF OBSTINATE VOMITING, AND AS A LOCAL ANÆSTHETIC FOR MINOR SURGICAL OPERATIONS.

BY E. STUVER, M.S., M.D.,
OF RAWLINS, WYOMING.

SEVERAL years ago, while treating a case of fever complicated by obstinate vomiting, the stomach rejecting everything taken into it, even small quantities of iced water, I first resorted to the use of cocaine muriate for the relief of this condition. One-eighth grain of the drug, in aqueous solution, administered about twenty minutes, or long enough to obtain its anæsthetic effect, before giving food or medicines, entirely relieved the vomiting, which did not recur during the illness. Since that time I have used cocaine in quite a large number of cases of various diseases for the relief of this aggravating, and at times serious, symptom. In a large proportion of the cases so treated the relief was prompt and satisfactory, but in others it was only transitory or entirely absent. In thinking over the subject it seemed logically conclusive to me that if cocaine could be combined with some remedy possessing analgesic and sedative effects, a more pronounced and persistent result would be obtained. Antipyrine, from its well-known influence in subduing pain, appeared to offer the greatest number of advantages for this purpose. Accordingly, for more than a year, I have treated cases of obstinate vomiting, whether due to central or to peripheral causes—vomiting caused by acute infectious or contagious diseases, as scarlatina, rubeola, etc., that due to acute indigestion, and other forms of gastric irritation, also the vomiting of pregnancy—by a combination of these two remedies, and have obtained better general results than by any other treatment; indeed, success often followed when our old, tried, and trustworthy remedies failed to afford relief. I trust, however, that no one will impute to me the claim of specificity for these remedies. They, like everything else, will fail at times, and this fact, in connection with their well-known potency, may render a caution against their indiscriminate use advisable, and impress the importance of carefully selecting cases in which the well-known physiological and therapeutic properties of the drugs are most clearly indicated.

The following cases will serve as examples of the effects produced:

CASE I.—On May 9, 1890, I was asked to prescribe for a woman suffering from obstinate vomiting of pregnancy. She had used all ordinary remedies without avail, and had become so weak that she could scarcely move about. She could not retain even a swallow of cold water. I gave the following:

R.—Cocaine muriate (P. D. & Co.'s)	12 grains.
Antipyrine . . .	1 drachm.
Water	6 ounces.

One teaspoonful to be taken every half-hour until vomiting was relieved.

This acted promptly and effectively, and she was much elated over the result.

CASE II.—S. B., aged seven years. In this patient every systemic disturbance causes irritability of stomach, nausea and vomiting. In April, 1890, while passing through an attack of parotitis the vomiting was very severe, and the stomach would retain nothing. I prescribed:

R.—Cocaine muriate (P. D. & Co.'s)	2 grains.
Antipyrine . . .	16 "
Water	2 ounces.

Of this she was directed to take half a teaspoonful every hour until vomiting ceased. A few doses produced the desired effect and she had no further trouble during the attack.

This child had a severe attack of measles about June 1st, attended during the pre-eruptive stage by obstinate nausea and vomiting, which were promptly relieved by a few doses of the same mixture.

CASE III.—On June 27, 1890, D. S., aged fourteen months, was suddenly taken with a severe attack of acute indigestion, attended by free emesis. Though the vomiting removed all, or the greater part, of the offending material, marked gastric irritability persisted and everything swallowed was promptly ejected. There was considerable fever (pulse 150), and intense thirst, which was aggravated by the inability to retain even small quantities of nearly ice-cold water. I gave $\frac{1}{24}$ grain cocaine and $\frac{3}{4}$ grain antipyrine in aqueous solution and repeated the dose in an hour. Fifteen minutes after taking the first dose the child drank water freely and suffered only slightly from nausea; a little later he nursed, and vomiting caused no further trouble. Two grains of calomel given in the evening produced free catharsis the following morning. This, together with the treatment above indicated, and careful regulation of the diet, were the only therapeutic measures employed, and resulted in a prompt and satisfactory recovery.

While the size of the dose and the frequency of administration have been varied to meet the exigencies of particular cases, I have obtained the best results from small, frequently repeated doses. My standard for an adult has been: cocaine ⅛ grain, antipyrine 1 grain, in aqueous solution every half-hour or hour as required.

While not pertinent to the subject just considered, I will take this opportunity to state that I have found concentrated solutions composed of five per cent. and fifteen per cent. each of cocaine and antipyrine, far superior as a local anæsthetic, to cocaine alone. The effect is more decided and much more persistent. I have used this solution with highly satisfactory results in minor surgical operations, also for obtunding the sensibility of the gums before extracting teeth. If, before the latter operation, this solution be thoroughly applied to the gums for about fifteen minutes, and the region of the external auditory meatus (a method first suggested, I believe, by a French physician) be well sprayed with ether, the extraction of teeth is attended by very slight pain.

For an external operation, where a more decided anæsthesia than can be obtained by simple application to the surface is desired, the effect can be greatly enhanced by applying the solution to the part to be operated on by means of a galvanic current strong enough to produce a decided impression. For this purpose a galvanic battery should be used, as it is needless to say the ordinary faradic battery or electro magnetic machine has but slight effect.

MEDICAL PROGRESS.

The Extraction of Unripe Cataract.—In the Berlin Medical Society, July 2, 1890, Professor Schweigger read a paper on this subject, discussing at some length the vague and varying views as to what constituted "ripeness," and claiming that the term and its practical outcomes are now largely obsolete. The importance of the matter, as is well known, lies in the question whether the lens can be wholly removed in the operation; for not only will portions of the unripe lens-substance cling to the capsule, and by their later opacity annul the benefits of the operation, but the presence of these swelling masses will often give rise to serious or destructive inflammations. The usual criterion, that the lens is opaque to the periphery, and that no shadow is cast by the iris in oblique illumination, he holds to be erroneous; since much time may be needlessly lost and the patient kept waiting in blindness for this stage, long after the eye is ready for the operation. He regards the age of the patient as the sole basis for judgment. In that period of life when the accommodation is annulled by the physiological changes in the lens, that is, toward the close of the fifth decade, and quite surely after the sixtieth year, we can extract any cataract as soon as defective vision makes the operation desirable, even if the greater part of the lens is still unclouded. In this case it is necessary to combine iridectomy with the extraction, and the old classical flap-operation with the retention of the normal pupil, to which Schweigger returned some years ago, finds here a valuable field. At earlier periods the question is more difficult, and the old criterion has weight. Total opacity is important, and here artificial ripening has its place: v. Graefe's discission, carried deep into the lens, being better before the fortieth year, but after that age Förster's trituration of the lens-cortex is preferable. Neither procedure needs iridectomy; and the extraction can generally be done from four to five days after the discission, or from one to two weeks after the trituration.

In the discussion, Professor Hirschberg, while concurring in most points, was still more radical. After the fortieth year any cataract is hard, or at least the nucleus is, and through an ample section any lens can be cleanly extracted whether the cortex is ripe, immature, or hypermature.—*Centralblatt f. prakt. Augenheilkunde*, July, 1890.

Ulcerative Stomatitis.—Dr. Nil J. Sokoloff (*Vratch*) describes an epidemic of ulcerative stomatitis in which he saw thirteen cases, all adults. In nearly all, the tonsils and posterior wall of the pharynx were simultaneously affected. The disease usually commenced with intense malaise, vomiting, diarrhœa, and fever. In severe cases the fever lasted during the whole course of the affection, its type on the whole resembling enteric fever, while in mild cases the temperature returned to the normal about the end of the first week. In some patients abscesses under the tongue, or in the organ itself, were observed; in two, an erythematous confluent rash occurred; in two, albuminuria was present. The liver and spleen remained normal in all cases. The duration of the affection varied between fourteen and fifty-six days. In one case direct infection was noticed—a patient who was recovering from some grave disease contracted ulcerative stomatitis from his neighbor. Bacterial examination revealed the presence of ordinary streptococci, but no specific microbes.

Professor Simanovsky also describes eight cases of the disease. In two of the cases the ulcerative process was confined to the mouth, while in the remaining six the fauces or the pharynx was involved. The faucial lesions were usually limited to one side, the ulcer being either on the tonsils or half-arches. In one of three cases in which the urine was examined, albumin was discovered. Search for bacteria gave negative results. The treatment consisted in gargling and painting with a solution of potassium chlorate (1 drachm to 4 ounces), a two-per-cent. solution of boric acid, or a solution of salol made by adding two teaspoonfuls of a six-per-cent. alcoholic solution to a glass of water.—*Journal of Laryngology and Rhinology*, August, 1890.

The Proper Time to Administer Quinine.—In the *Annales de Thérapeutique Médico-Chirurgicales*, July, 1890, Charpentier gives the following directions as to the administration of quinine:

1. The action of quinine is chiefly felt about six hours after its ingestion, and for this reason it should be given, not at the time of an expected malarial paroxysm, but six hours before.

2. In the case of quotidian fever the quinine should not be given six hours before the chill, but eight hours before, so that the full effect may be present two hours before the chill, for though the chill is the apparent onset, the real onset is still earlier.

3. When the fever is tertian, Charpentier thinks that the quinine should be used twelve hours before, and where it is quartan, eighteen hours before the attack is expected.

The drug should be given in massive doses, not in fractional doses, for the reason that it is rapidly eliminated by the urine, and in small amounts would have no effect; although when the stomach is too irritable to stand heroic amounts, fractional doses should be given every three-quarters of an hour.

Treatment for Ozæna.—COZZOLINI recommends the following powder for the treatment of this troublesome affection:

R.—Salol	2 drachms.
Boric acid	1 drachm.
Salicylic acid	12 grains.
Thymol	5 "
Powdered talc	3 "

Use as an insufflation.

—*Provincial Medical Journal*, August, 1890.

Theobromine as a Diuretic.—GRAM, in the *Annali di Chimica e di Farmacologie*, xi., 1890, sums up his opinions of this drug as a diuretic in heart and renal disease as follows:

1. Theobromine when pure is absorbed with difficulty, but its absorption is followed by pronounced diuresis. It is without action on the heart and provokes diuresis by a direct action on the kidneys.

2. If salicylate of sodium is combined with theobromine it facilitates the absorption of liquids and increases their elimination. The effects of theobromine are not disagreeable and the author noticed only one instance in a weak subject in which vertigo occurred.

The ordinary daily dose is 1½ drachms of the salt divided into 15-grain doses.

Retinol in the Treatment of Vaginitis.—BALZER, in the *Revue Obstétricale et Gynécologie*, July, 1890, writes of retinol, which is extracted from colophony by distillation. It is a hydrocarbon which presents itself in the form of a liquid of the consistency of linseed oil, and of the color of tan—dark-brown, or sometimes golden-yellow, according to its mode of preparation. Its reaction is acid and it evaporates slowly at ordinary temperatures. It is balsamic in nature, and possesses antiseptic powers. It has been used in America in gonorrhœa and metritis and similar diseases. When used in vaginitis it may be applied to the mucous membrane by means of an applicator and speculum, or on a tampon, and is particularly useful where vegetations are growing or recur after removal. When used on a tampon an excess acts very severely, and it is often best used by making it into a paste with boric acid and introducing a ball of this into the vagina or against the diseased spot. As the paste is very diffusible it may in some cases produce a good deal of pain and even intense inflammation.

So far, Balzer has not employed retinol sufficiently to recommend its use, but he expects to prove that it is valuable as an antiseptic, and as a cauterant and local application in certain cases of diseased mucous membranes.

Bromidrosis of Feet.—SCOTT recommends the following:

R.—Biborate of sodium, Salicylic acid	of each 2 drachms.
Boric acid	30 grains.
Glycerin at 86° F., Alcohol	of each 1 ounce.

Mix, and use as a wash three times a day.

This application is particularly useful in those cases where much maceration of the skin is present, and where remedies of other kinds have failed.

Amylene Hydrate in Epilepsy.—NACHE agrees with Wildermuth as to the value of amylene hydrate in epilepsy, even where bromides have failed, and where the attacks are not only very frequent but severe. He uses a 10-per-cent. solution of the drug, and gives from one to two tablespoonfuls a day (from 30 to 90 grains). Nache also believes that *petit mal* and nocturnal epilepsy are benefited by the drug.

Operative Treatment of Bubo.—PÖLCHEN, of Königsberg, gives the following directions for the treatment of bubo produced either by gonorrhœa or chancre:

After all antiseptic precautions are taken the bubo is to be incised in a line parallel to the longitudinal axis of the body, and not parallel to Poupart's ligament. The length of the incision should be about that of the swelling. After the gland is exposed, it is to be carefully dissected away from the surrounding tissues, care being taken to avoid the great vessels, and every portion of diseased tissue removed. The space surrounding the gland is now to be packed with iodoform-gauze while search is made for other diseased parts. At this time the hæmorrhage should be almost nothing. For the total destruction of the disease-process we may cauterize all the affected glands with caustic potash, using antiseptic gauze to protect the healthy parts, instead of scraping the glands. The advantages of the latter plan consist in the ease of the operation and its freedom from danger, while it is asserted that the dangers from general infection are much decreased by the action of the caustic and that the cure is completed in the majority of cases without fever. It is true, on the other hand, that healing is postponed a little longer than after the simple use of the knife. This inconvenience, is however, counter-balanced by the fact that the patient can return to his usual occupations almost at once, and the secretion from the wound amounts to almost nothing.

Treatment of Syphilis by Rectal Injections of Iodides.—According to the *Revue Générale de Clinique et de Thérapeutique*, the following formula may be used by the anus, whenever the stomach is disordered:

R.—Iodide of potassium	15 grains.
Extract of belladonna	¼ grain.
Water	4 ounces.—M.

The solution must be warm, and is said to be well borne and effective.

Treatment of Metrorrhagia by Ergotine Injections.—When ergotine is badly tolerated by the stomach, it is recommended that it be used in the following manner in metrorrhagia:

The bowel having been first evacuated of fæcal matter and the rectum washed out, a teaspoonful of the following is to be mixed with two tablespoonfuls of hot water and injected:

R.—Ergotine	150 grains.
Distilled water	2½ ounces.
Glycerin	6 drachms.
Salicylic acid	6 grains.

—*Revue Gén. de Clin. et de Thérapeutique*, Aug. 6, 1890.

Treatment of Acne.—In the *Revue Thérapeutique Médico-Chirurgicale*, ISAACS recommends the following for acne:

R.—Camphor, Vaseline, Beta-naphthol, of each	150 grains.
Precipitated sulphur	1½ ounces.
Green soap	½ ounce.—M.

Apply to the affected part for from three to fifteen minutes, according to its susceptibility. After using this lotion, use in its place, after thoroughly drying the skin:

R.—Resorcin, Salicylic acid, of each	7 to 15 grains.
Oxide of zinc	30 grains.
Vaseline	6 drachms.—M.

This is to be allowed to remain on all night, or a less time if it is too stimulating, and is itself to be followed by an emollient, such as cold cream or chalk powder.

Prescription for Flatulent Dyspepsia.—DR. PAUL CHÉRON prescribes the following powder to cases of flatulent dyspepsia:

R.—Magnesia, Calcium phosphate, Powdered charcoal, Sulphur, equal parts.	

A teaspoonful to be taken in water when necessary.—*Provincial Medical Journal.*

Hypodermic Injection for Delirium Tremens.—In *La Semaine Médicale*, July 30, 1890, the following formula is given:

R.—Methylal	75 grains.
Distilled water	5 ounces.

Mix, and use for hypodermic injections.

This mixture is to be injected, hypodermically, in three or four doses during twenty-four hours, and its use continued for four or five days. It produces less evil effects under these circumstances than most of the drugs devoted to the treatment of delirium tremens. Fischer states that these injections are never followed by abscess, and may be employed when an attack of *mania-a-potu* is imminent, as a prophylactic measure.

Tests for Arsenic in Wall-paper.—The *British Medical Journal* describes the following simple tests for arsenic in wall-papers: Turn down an ordinary gas-jet until the flame is wholly blue. Then a strip of the suspected paper, about one-sixteenth of an inch wide, is brought in contact with the outer edge of the flame. If arsenic is present, a gray coloration will be seen in the flame, and, if the paper is burned a little more, a garlic-like odor can be detected in the fumes. If, on removing the paper from the flame, the charred portion is of a reddish color, copper is present (arsenic used for this purpose is usually in the form of arsenite of copper). On again placing the charred paper in the flame a green coloration, due to the copper, is seen.—*The Sanitarian*, July, 1890.

Treatment of Acute Vaginitis.—In the *Revue Générale de Clinique et de Thérapeutique*, July 2, 1890, ELOY gives the following treatment for vaginitis: He divides the disease into the initial or primary stage, and terminal or final stage.

For the primary condition he advises the employment of hot injections of liquid vaseline and cocoa-butter, combined with 300 grains of boric acid to each pint of this mixture, the injections to be made every few hours. This is to soothe the irritated parts.

In the terminal stages, when acute inflammation has passed, one of the following injections is useful:

Sulphate of iron	300 grains.
Distilled water	1 pint.

Or,

Chloral	300 grains.
Distilled water	1 pint.

Or,

Permanganate of potassium	2½ grains.
Distilled water	1 pint.

After several days, if the discharge persists, the vagina should be packed with cotton tampons saturated with glycerole of tannin made as follows:

R.—Tannic acid, Glycerin, of each	2 drachms.

After each removal of these, the mucous membrane should be touched with a strong solution of silver nitrate.

Nylander's Test for Glycosuria.—DR. BRANDRETH SYMONDS advocates the use of Nylander's solution in testing for sugar in the urine (*New York Medical Journal*, July 12, 1890). The solution consists of bismuth subnitrate, 31 grains (2 grammes); Rochelle salt, 62 grains (4 grammes), dissolved in 3⅓ ounces (100 c. c.) of a 10-per-cent. solution of sodium hydrate. On boiling this with glucose a dark-brown or black precipitate of bismuth suboxide and metallic bismuth is produced. The most delicate mode of applying the test is to half-fill a test-tube with urine, then add about one-third of the solution. Boil the upper layers, watching for any reduction.

Though less delicate than Fehling's test, detecting only a tenth of one per cent., it has the advantages of not changing, even when kept for a long time, and of not giving a reaction with chloral, pyrocatechin, or glycosuric acid. Dr. Symonds thinks the test sufficiently delicate for ordinary clinical work, and is the one which he usually applies.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

PURULENT CAPILLARY BRONCHITIS IN THE PHTHISICAL, DUE TO THE PNEUMOCOCCUS.

EVERY physician of large clinical experience with the phthisical must have observed many cases in which the more or less sudden termination has seemed to be due to something above and beyond the mere tuberculous condition. That is to say, either physical examination fails to show—and autopsy to reveal—an extent of pulmonary infiltration or destruction sufficient to necessitate a fatal issue at that time, or even to account for the severity of the constitutional symptoms; or, on the other hand, while conditions of great pulmonary destruction have long been recognized, yet the final breaking-down of vital powers in general, is of a suddenness not to have been expected from the slow progress of the chronic disease. The most plausible explanations hitherto offered for the phenomena are sudden, generalized infection from penetration of bacilli into the circulation, or lethal intoxication with ptomaïnes.

An investigation recently undertaken by MM. DUFLOCQ and MENETRIER (*Archives Générales de Médecine*, June and July, 1890) throws a certain amount of new light upon the subject. In the course of their researches into the pathogenetic activities of the pneumococcus, other than as the cause of pneumonia, they have observed clinically, and examined post-mortem, a number of cases of phthisis, upon which an acute capillary bronchitis had supervened, apparently from secondary infection, which they attribute to the pneumococcus.

At the autopsy they have invariably found the lesions of the tuberculous and bronchitic infections coëxisting, but not coëxtensive; the anatomical relations being such as to leave no doubt of the priority of the tuberculous process. While the lesions of tuberculosis were found principally in the upper lobes, the capillary bronchitis involved the middle and inferior portions of the lung; that is to say, regions relatively free from bacillary localization. The bacillus was always wanting in the pus of the bronchioles, while the pneumococcus was encountered only exceptionally and in very small number, in the liquid contents of cavities. Having determined beyond doubt, by culture and by inoculation, that they were dealing with the veritable pneumococcus, the authors ask, Why is it that this microbe gave rise in the cases under consideration, not to pneumonia, but to capillary bronchitis? The answer they give is, in brief, that while ordinarily the pneumococcus must act in conjunction with other pathogenetic parasites—as, for example, the streptococcus or the pneumo-bacillus of Friedländer, or some more common pyogenetic germ—yet in these particular cases it was the sole agent in the infection; the irritation produced by the presence of the tubercle bacillus and the passage of tuberculous fluids over the bronchial mucous membrane having rendered the tissues vulnerable without other intervention.

If these observations are correct, it will readily be seen how a comparatively limited and quiescent pulmonary tuberculosis can be suddenly converted by this additional infection into a very grave and dangerous condition. Such additional infection will explain the heightened fever, the renewed symptoms of septic toxæmia, and the physical signs of obstructed respiration and impaired circulation disproportionate to the extent of the existing tuberculous lesion.

In these remarks, as in the researches quoted, the well-known liability of the subjects of slow, chronic phthisis to sudden and frequently fatal pneumonia has not been under consideration.

STOMACH-WASHING IN CHILDREN.

STOMACH-WASHING in the treatment of the gastric disorders of childhood has been practised chiefly by

Epstein, and in this country, to a limited extent, by Seibert and a few others. Recently Dr. William D. Booker (*Johns Hopkins Hospital Bulletin*, July, 1890) has used the method in the treatment of nearly two hundred cases of gastro-intestinal disturbances in children, all the cases occurring in hospital or dispensary practice. Although, as Booker himself writes, it is too early to estimate the exact position of the procedure in the therapeutics of childhood, it is undoubtedly of great value in the treatment of certain conditions.

Booker's observations seem to show that stomach-washing is of especial value for the relief of vomiting due to indigestion. In many of his cases relief was immediate, and in only one case was it necessary to stop giving milk. The vomiting of dysentery was less markedly influenced, though in some cases it was checked. In the summer diarrhœas benefit often followed the washing, and was evidently due to the fact that undigested food was prevented from entering the intestines. In some of the latter cases, however, the curative influence was very slight. A few cases of constipation due to gastro-intestinal catarrh were also improved by systematic stomach-washing.

The apparatus used by Booker was a Nélaton catheter, No. 8, 9, or 10, attached by a rubber tube two feet long to a two-ounce glass funnel. To perform the operation properly the child should be held in a sitting position on the nurse's lap, with the head slightly inclined forward and the hands confined by the nurse's left arm. The tube, moistened with water, is then steadily passed back to the pharynx and downward into the stomach. Gagging may be produced when the end of the catheter reaches the pharynx, but usually ceases when it reaches the stomach. One or two ounces of water are then poured into the funnel, held above the child's head, and the moment the funnel becomes empty it is lowered and the contents of the stomach siphoned out. This should be repeated until the water returns clear.

Booker also made some interesting observations upon the contents of the stomach in normal and in disordered digestion, but it is to the therapeutical aspects of the subject that we wish to direct attention, and to advise washing out the stomach in the treatment of gastro-intestinal diseases in children, *after* careful regulation of the diet and other measures have failed. We do not believe that it will, or should, supplant other methods of treatment, but that it is a valuable addition to our resources in the management of serious and often obstinate diseases.

THE NEW SURGEON-GENERAL.

Dr. Jedediah H. Baxter, formerly Chief Medical Purveyor of the United States Army, has just been appointed its Surgeon-General, and we congratulate the President upon his wisdom in making such an appointment. While it has been claimed by certain opponents of Dr. Baxter that he has never seen much active frontier service, it nevertheless remains a fact that such service is not the training necessary to make a good surgeon-general, who needs executive ability and experience in matters closely connected with what Dr. Baxter has been accustomed to attend to since the war. Further than this, his prolonged residence in Washington has given him complete information as to the central management of the service, and his executive ability must soon make itself felt now that he has succeeded Surgeon-General Moore, and has at last reached a rank where he may use his powers. Promotion according to rank is a custom too often disregarded, and we are glad that in this instance at least the regular line of promotion was followed out. Dr. Baxter has before him a period of many years before the retiring age arrives, and we are confident that these years will be used for the good of the service.

SPECIAL CORRESPONDENCE.

THE POLICY OF SURGEON-GENERAL BAXTER.

To the Editor of The Medical News,

Sir: On the 28th ult. the Senate wisely confirmed the appointment of Colonel Jedediah H. Baxter to the Surgeon-Generalship of the United States Army, vice Surgeon-General John Wood, retired. General Baxter's service of over thirty years in the Army, twenty-five of which were in the administrative department, his sequence in line of promotion, and his well-known ability amply warrant the appointment.

The long period during which Dr. Baxter will fill the highest office within the medical department of the Army renders the lines upon which the service will be conducted a matter of interest beyond the circle of army surgeons. Your correspondent, therefore, is happy to be able to assert authoritatively, that increased effort will be made to improve the efficiency of this arm of the service.

To this end, examinations for admission to the service will aim to test more thoroughly than heretofore the practical ability of the applicant, rather than his fund of theoretical knowledge, and in all cases a sound general education will be an essential for appointment. Previous hospital experience will rate more highly than heretofore in an applicant's qualifications, and will be esteemed

in accordance with its length and the standing of the institution. The physical condition of the applicant will be inquired into as strictly as is the case in other arms of the service. The necessity of this measure has been evinced by the proportion of appointees who, after a few months of active service, become physically disqualified.

Another plan that cannot fail of excellent effect is, that assistant surgeons after a reasonable term of service at isolated posts shall be given leave of absence for the purpose of "brushing up" their medical knowledge by attendance at post-graduate and hospital courses in the larger cities.

Rapid promotion and the consequent increased pay will render the position of army surgeon more attractive and induce an increased number of applicants. With this object in view, it is Surgeon-General Baxter's intention to secure the adoption of measures that will enable disabled surgeons to enter upon the retired list without the vexatious delays now experienced, and thus reduce the number of contract-surgeons employed. When the latter are required, a much more strict preliminary examination will be enforced than has been the custom in the past.

These are but a few of the many plans Dr. Baxter entertains for the benefit of the department of which he is the head. Many others concern minor matters of detail of little general interest, others are not yet sufficiently developed to entitle them to publication; but that all will prove for the benefit of the service and for the welfare of its officers, the long experience and tried ability of Dr. Baxter are ample guarantee.

WASHINGTON, D. C., August 30, 1890.

BRIGADIER-GENERAL J. H. BAXTER was born in Strafford, Vermont, May 11, 1837. He is the son of the late Hon. Portus Baxter, who represented the Third District of Vermont in Congress during the War of the Rebellion.

General Baxter was graduated from the University of Vermont, receiving the degree of A.B. in 1859, and that of M.D. in 1860. He is also a graduate of the Law Department of the Columbian University of the District of Columbia.

Dr. Baxter entered the army at the outbreak of the war, as surgeon of the 12th Massachusetts Regiment of volunteers, and was mustered into the United States service June 26, 1861. He has been in continuous service in the volunteer and regular army from that time.

He was promoted to be Brigade Surgeon, U. S. Volunteers, April 4, 1862, and served in the Peninsular campaign with the Army of the Potomac, on the staffs of Generals Banks and McClellan. He was taken ill with fever while on duty in the field and ordered to Washington.

Having partially recovered, he was assigned to the charge of Campbell Hospital, Washington, D. C., one of the largest United States General Hospitals during the war. He organized the hospital, which contained about 1500 beds, and was in full charge until January, 1864, when he was called by the order of the Secretary of War Stanton to take charge of the medical department of the Provost Marshal General's Bureau, at the request of General James B. Fry, the Provost Marshal General.

On the reorganization of the regular army on a peace-footing, after the close of the war, the services of volunteer officers who had achieved distinction during active service were recognized in filling original vacancies created by Congress in the several staff departments, which had been increased commensurate with the growth of the standing army.

Surgeon Baxter was appointed Assistant Medical Purveyor, with the rank of Lieutenant-Colonel, July 20, 1867, and March 12, 1872, was appointed Chief Medical Purveyor with the rank of Lieutenant-Colonel; and Chief Medical Purveyor with the rank of Colonel, June 23, 1874.

He has been the senior officer in the Medical Department, next to the Surgeon-General, for many years, and on the retirement of Surgeon-General Moore, August 16, 1890, the President, on the same day, sent to the Senate the name of Colonel Baxter to fill the vacancy. He was unanimously confirmed by the Senate, August 27th.

SOCIETY PROCEEDINGS.

THE GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, April 18, 1890.

THE PRESIDENT, JAMES H. ETHERIDGE, M.D., IN THE CHAIR.

DR. FRANKLIN H. MARTIN exhibited a cancerous uterus that he had removed by vaginal hysterectomy. The cervix was first thoroughly scraped away to as near the healthy tissue as possible. In about three weeks the disease returned. When it began to involve the vagina, Dr. Martin advised the operation of vaginal hysterectomy, which was done, January 15, 1890. The bases of the broad ligaments were ligated with silk, and for the remaining portion of each broad ligament clamp-forceps (Byford's pattern) were used. The operation was performed without difficulty or complications, and the patient was discharged in about four weeks. On April 16th, there was still no recurrence.

DR. HENRY T. BYFORD then showed a suppurating kidney. The patient was thirty-one years old; married for five years, and had had no children. She had been subject to periodic attacks of septic fever for more than a year. The temperature would reach 103° to 104° F. during the attack, with great tenderness in the right side of abdomen. After a discharge of pus and granular material with the urine, the symptoms would subside for a time. The organ was felt to be enlarged at each examination.

The kidney was removed through an incision made in the linea semilunaris, through which the other kidney was first palpated and found to be healthy. The tissues about the diseased one were healthy, but the uterine appendages were extensively diseased. He completed the operation by establishing drainage with iodoform-gauze through a small opening in the lumbar region, and closed the abdominal incision completely. The

ureter was ligated with fine silk at about one and one-half inches from the kidney, and placed so that any suppuration that might arise from it would find its way out through the lumbar opening. The temperature remained between 99° and 100° F. for a few days, and then became normal.

Dr. Byford also showed a specimen of probable sarcoma of the uterus and one of fibroma of the uterus. The patient with the sarcoma was at about the period of the menopause. The tumor was growing rapidly and causing pain, and the bloodvessels about the uterus were exceedingly large. He based his diagnosis upon the appearance of the tumor, the excessive vascularity, the absence of a capsule, and the manner in which it was attached to the bladder. Microscopical examination had not yet been made.

In the case of the fibroma, the diagnosis was obscure. Ten years previously the condition had been diagnosed and treated as pelvic inflammation and pyosalpinx. The abdomen, when the patient was seen by Dr. Byford, was so tympanitic that it was impossible to make a satisfactory bimanual examination. The patient was taking liquor and opiates, was very nervous, and was losing ground. This was the sixth case that Dr. Byford had operated upon by the following method:

The broad ligaments are tied off, the uterus amputated below the tumor, and the stump sewed up somewhat after Schröder's method, but with catgut and silkworm-gut. The bladder is separated, and an opening made into the vagina through the anterior fornix at the junction with the cervix. The silkworm-gut sutures are used for traction, and the cervix is drawn down and forward into the vagina and a clamp put on through the vagina. He usually holds the stump loosely with clamps, so that the apposed surfaces may heal up, as after trachelorrhaphy. As in all his earlier cases but the second the edges sloughed, he now prefers ligating rapidly with silk, and clamping firmly with a hollow clamp, so that the slough will separate early and come off in the clamp. The clamp prevents the contact of the slough with the patient's tissues, and avoids septic trouble.

After the stump is turned down he sews the peritoneum from behind the bladder to the posterior wall of the cervix. There is no raw surface left for extensive adhesive inflammation in the pelvis, with its consequent peritonitis and obstruction of the bowels. He has used drainage in all of the cases but one, because he does not usually operate on simple fibroids, there being generally some disease in the broad ligament and an oozing surface left. When he puts on the clamp from below he inserts a finger from above in the cul-de-sac of Douglas behind the cervix and a thumb in front of it, then pushes a pair of hæmostatic forceps up from the vagina through the anterior fornix between his thumb and the cervix, and enlarges the rent by scissors-snipping and stretching.

In discussion, DR. PARKES said that he regarded the specimen of kidney as very interesting and unusual in the length of time that it had existed without following the usual disposition of such diseases toward external suppuration. The only explanation of this is the peculiar enlargement of the ureter, which enabled it to carry the accumulated matter in the pelvis of the kidney into the bladder. Usually in suppurating kidney almost the first manifestation is the formation of a tumor and the development of a perinephritic abscess which opens externally. Surgeons have always found difficulty in the removal of such kidneys, on account of the surrounding cicatricial tissue. It is almost a rule, he said, that suppurating kidneys should not be removed, and this rule is sustained by the results in many cases. But this case was very exceptional in that there were no surrounding complications; all the trouble was inside the kidney and could be attacked without the usual difficulties. He had always dreaded to remove them, on account of the complications arising from the presence of adhesions and the danger of septic poisoning, and has adopted the plan of laying them widely open, which is not very satisfactory, as the patient often apparently recovers, but the disease returns, owing to the many pockets in which pus accumulates. The idea of continuous irrigation has suggested itself to him in these cases.

DR. MARTIN said that he had had the pleasure ot witnessing two of these operations by Dr. Byford with his method of treating the stump. The only objection that could be offered to the operation is that, for a nervous, rapid operator, the procedure is altogether too long. Dr. Byford spends from two and a half to three hours in performing this operation, and the abdominal cavity is perfect after the stump is secured.

In the discussion which followed a paper by DR. T. J. WATKINS on the

AFTER-TREATMENT OF ABDOMINAL SECTION,

DR. JAGGARD said that he was particularly interested in the allusion to ether as a renal irritant, and the reader's reference to two cases in which ether was responsible for fatal nephritis. Dr. Jaggard thought that this was one of Emmet's ideas and that the evidence that ether was a renal irritant had never been proven. Dr. Weir, of New York, has published a very interesting paper on the effect of ether upon the kidneys, and the results show that ether employed as an anæsthetic is not a renal irritant. In not one case has Dr. Weir been able to establish the fact that ether produces more irritation of the kidney than does any other extremely volatile substance. It would be interesting, he said, if Dr. Watkins would give the evidence upon which he based his conclusion that ether was responsible for two cases of fatal nephritis. Can he exclude septic infection? Dr. Jaggard also said that he had used ether in a number of cases of puerperal convulsions, contrary to the teaching of Emmet, and that he had never seen bad effects. He considers ether given hypodermically a valuable diffusible stimulant in chloroform-narcosis, and has never seen local irritation when the hypodermic needle was sterilized.

In regard to the length of time that a woman should remain in bed after an abdominal section, he described two cases. In one the woman, two weeks after the operation left her bed, travelled five miles in a carriage, and, a week later, died of peritonitis. In the other case the woman went home by railway, eighteen days after the operation. On the journey the incision opened and the intestines protruded. The incision was closed again by her family physician, and she recovered.

DR. PARKES referred to the fact that after abdominal section the temperature might rise even to 104°, from no

other cause than constipation. In such conditions he does not believe that the administration of antipyretics is proper, though, if there are general symptoms such as malaise and headache, he advised cold sponging.

Dr. Dudley spoke of the management of abdominal section in the Woman's Hospital of New York, when he was an interne in the institution, fifteen years ago. At that time patients were kept on a restricted diet during the week preceding the operation. They were also given large doses of quinine, and, to prepare the system for the shock of the operation, large doses of opium. These drugs were continued after the section. The percentage of deaths was enormous, though, of course, many died from the absence of asepsis.

Dr. Dudley also said that he had adopted the enema—a half-ounce each of glycerin, sulphate of magnesium, and water—recommended by Dr. Watkins for the treatment of tympany, and that it had proven very satisfactory.

Dr. Byford said that he had frequently noticed that a patient who had been long under ether—two or three hours—was less likely to vomit than a patient who had taken comparatively little ether. He did not consider it a good rule to take out the drainage-tube in twenty-four hours, nor did he think that the stitches should be removed in six days.

In closing the discussion, Dr. Watkins said that he still adhered to the belief that the drainage-tubes should be removed early, for, if fluid remains in the abdominal cavity, it will well up through the track of the tube.

He was unable to see any reason for the opinion expressed that etherization does not produce nephritic congestion. No one doubts that ether is eliminated by the kidneys, and that when given in small amounts it has an active diuretic effect. It is, moreover, a therapeutic fact that all active diuretics, when given in excess, produce nephritic congestion. Scanty secretion of urine, pain in the region of the kidneys, nausea, and cephalalgia not infrequently follow etherization, and these symptoms are usually relieved by increasing the functional activity of the kidneys.

In regard to the method of etherizing, he said that, though the Clover inhaler is theoretically bad, practically it works well. When properly used, not more than two ounces of ether are necessary for the first hour, and frequently one ounce suffices for an operation. The liability to vomit is much lessened when little ether is used, and congestion of the kidneys and air-passages is necessarily much less frequent.

CORRESPONDENCE.

LONDON.

The Annual Meeting of the British Medical Association. The Address of the President. Mr. Lawson Tait's Address. Professor Hamilton on Acid Dyspepsia.

To the Editor of The Medical News,

Sir: The annual meeting of the British Medical Association has, of course, been overshadowed by the International Congress at Berlin; but, nevertheless, the gathering at Birmingham was one of considerable importance, and deserves some recognition. In the first place, it was evident that the ill-feeling in a certain quarter last year against the Association, which led to the resignation of some seventy members, had not had any permanent damaging effect on the Association. Dr. Wade, one of the oldest practitioners, and certainly the most distinguished physician in Birmingham, was elected President and worthily upheld the dignity and traditions of the office. His address dealt almost entirely with medical education, the important medico-political problem of the day. The General Medical Council has, in its wisdom, decreed that at no very distant date the medical curriculum shall be at least five years, instead of four, as at present, and has proposed a scheme by which the first year shall be entirely devoted to physics, chemistry, biology, etc. Dr. Wade is not quite satisfied with this arrangement, and would like to see two years devoted to the study of the preliminary sciences, as we may call them. He thinks that the study of these subjects should be commenced at the age of fifteen, as by that time a boy has had ample opportunity for a sufficient general education. One difficulty with this plan is that the majority of boys at the age of fifteen have not decided what profession to follow. In cases where they have arrived at this decision, there can be no question that it is greatly to their advantage to begin the study of the sciences at an early age.

As to the main question of what is to be done during the additional year, I am in hopes that the time will be added to the end and not to the beginning of the curriculum, for I am quite sure that our students are much more in need of additional clinical work than of preliminary study, and I would make the extra year count only from the time of passing the final examination. So long as students have an examination before them the majority will make no attempt to learn anything but what is necessary to enable them to scrape through the examination; and it is my firm conviction that the addition of a year at the commencement of the medical curriculum will not make them one whit better practitioners than they are under the present *régime*.

Mr. Lawson Tait, who delivered the Address in Surgery, which, it goes without saying, was both vigorous and practical, denounced very strongly the unpractical character of the teaching of the present day and the enormous amount of time wasted upon the biological training of the modern student. He would like to return to the old system of apprenticeship; but, although many of our leading practitioners of the present time were educated under that *régime*, and are never weary of advocating it, I do not anticipate that it will ever be reintroduced. If a system of apprenticeship at the end of the curriculum could be established, it would, I believe, be of great service.

One of the most important papers read at the meeting was that of Professor Hamilton, of Aberdeen, on "Acid Dyspepsia." His main point was that the disturbance was, in the first instance, one affecting mainly the quantity or the quality of the gastric juice. Variations in the quantity of the hydrochloric acid in the gastric juice are exceedingly common, and it is chiefly on these variations that the symptoms of dyspepsia depend. The second cause arises from a deficiency in the quantity of hydrochloric acid and the formation of lactic acid in

excess. Normally, lactic acid is formed in only very minute quantities. So that acid dyspepsia may be the natural consequence of a too abundant formation of hydrochloric acid in the stomach, or of a deficient formation of it; and the recognition of these two forms is, of course, all important in treatment, as it is obvious that they will require different measures.

An active discussion followed Sir Dyce Duckworth's paper on "Functional Disorders of the Heart."

Of course, the social festivities and entertainments were not neglected at this meeting, and the hospitalities of the Mayor and other local celebrities cannot have failed to leave a pleasant recollection on the minds of the twelve hundred members who received them. This is the fourth time that Birmingham has been the meeting-place of the Association; and since its last meeting there, seventeen years ago, the Association has trebled its membership, now including in its roll more than half the practitioners in the United Kingdom.

NEW INVENTIONS.

A NEW SET OF REFRACTION LENSES.

By H. F. HANSELL, M.D.

I have recently had made a set of test-lenses adapted to the needs of medical men who do not practise ophthalmology as a specialty. It contains comparatively few lenses (50—Natchez 212), yet so arranged that, either singly or in combination, all practical strengths of sphericals and cylinders may be obtained, and all remediable errors of refraction corrected. The advantages are low cost, light weight, and small size; the single disadvantage is the slightly greater expenditure of time necessary in adjusting the lenses, as compared with the larger cases.

The plus and minus spherical lenses are pairs of 0.25 and 0.50, singles of 0.75, 1, 1.50, 2, 3, 4, 8, 13; cylinders, singles of 0.25, 0.50, 0.75, 1, 1.50, 2, 3, 4; prisms, 1°, 2°, 4°, 8°, 20°. The box contains a Natchez frame so modified that it will hold in position four lenses on each side at the same time. The case is made and sold by Borsch & Rommel, 1324 Walnut St., Philadelphia.

NEWS ITEMS.

Examinations for Appointment in the Medical Corps of the United States Army.—An army medical board will be in session in New York City during October, 1890, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the board will make application to the Secretary of War, before October 1, 1890, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college; as evidence of which, his diploma must be submitted to the board.

Further information regarding the examinations may be obtained by addressing Surgeon-General J. H. Baxter, U. S. Army, Washington, D. C.

Foreign Students in France.—The *Gazette Médicale de Paris* gives the following figures in regard to this question: The foreign students registered in the faculties of medicine for the scholastic year of 1889–90 numbered 908. Of these Paris has 822, made up as follows: 6 Germans, 51 English, 7 Austrians, 7 Belgians, 8 Bulgarians, 34 Spanish, 34 Greeks, 6 Dutch, 12 Italians, 1 Norwegian, 18 Portugese, 85 Roumanians, 261 Russians, 25 Swiss, 71 Turks, 159 Americans, 13 Egyptians, 1 Persian, 1 Australian.

Bordeaux has 17 foreign students, of whom 2 are English, 2 Belgians, 1 American, 1 Egyptian, 5 from Mauritius, 5 from Argentine Republic, and 1 from Cuba.

Lille has 3 foreigners: 1 English and 2 Russians.

Lyons has 8 foreigners, namely, 1 Russian, 2 Swiss, 3 Turks, 2 Egyptian.

Montpelier has 53 foreigners: 2 English, 14 Bulgarians, 3 Spaniards, 7 Greeks, 1 Italian, 2 Roumanians, 4 Russians, 16 Turks, 4 Egyptians.

Nancy has 4 foreigners, namely, 3 German and 1 American.

In *résumé* we have 907 foreign students, as follows: 9 Germans, 56 English, 7 Austrians, 9 Belgians, 22 Bulgarians, 37 Spaniards, 41 Greeks, 6 Dutch, 13 Italians, 1 Norwegian, 18 Portugese, 87 Roumanians, 268 Russians, 27 Swiss, 90 Turks, 161 Americans, 19 Egyptians, 5 Mauritians, 1 Persian, 1 Australian, 5 Argentine Republicans, and 1 Cuban.

American Rhinological Association.—The American Rhinological Association will hold its eighth annual session at Louisville, Ky., October 6, 7, and 8, 1890.

Many subjects relating to nasal and naso-pharyngeal diseases will be opened for discussion by Fellows of the Association. The medical profession is cordially invited to attend.

The Secretary, Dr. S. Knode, Omaha, Nebraska, will furnish any information to physicians desiring to become members.

Dr. John K. Mitchell has returned to Philadelphia after a long absence made necessary by an attack of typhoid fever last autumn, and has moved into a new office at No. 211 South Seventeenth Street.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 30, 1890.

Hoehling, A. A., *Medical Inspector.*—In addition to present duties, ordered as President of Medical Examining Board at Philadelphia, convened by Department Order, June 9, 1890.

Kennedy, R. M., *Assistant Surgeon.*—In addition to present duty, ordered as member of the above Board.

Ogden, F. N., *Passed Assistant Surgeon.*—In addition to present duty, ordered as member of the above Board.

McClurg, Walter A., *Surgeon.*—Granted a month's leave of absence from September 1st.

Kershner, Edward, *Surgeon.*—Granted two weeks' leave of absence from September 1, 1890.

ORIGINAL LECTURES.

REMOVAL OF AN INTRA-LIGAMENTARY CYST.

A Clinical Lecture,
delivered at the Hospital of the University of Pennsylvania.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY.

[Reported by LEWIS H. ADLER, JR., M.D.,
RESIDENT PHYSICIAN OF THE EPISCOPAL HOSPITAL; LATE RESIDENT PHYSICIAN OF THE UNIVERSITY HOSPITAL.]

GENTLEMEN: The woman I bring before you this morning is thirty-seven years old. She has been married thirteen years, but has been sterile, and she has a tumor which developed eighteen months ago. Examination shows what seems to be a multiple fibroma of the uterus, together with another abdominal tumor, the nature of which I have not yet determined. The fact that she has uterine fibroids suggests that the growth is fibro-cystic; but, as this is rare, and as the tumors are separated from each other, I am more inclined to think that it is an ovarian growth. If it is fibro-cystic, it is more serious. The strongest reason against its being a fibro-cystic tumor is that there is no increase in the amount of the monthly bleeding. Whatever it is, I propose to cut into the abdominal cavity, in order to see what can be done in the way of removal. The amount of fat in the abdominal walls is small, and this circumstance renders the operation easy.

Just here, whilst the patient is being etherized, allow me to say a few words about the preparation of a patient for an abdominal section.

In the first place, all the emunctories of the body should be active. If the patient has travelled a long distance, rest in bed and tonics are indicated; if the patient is strong, moderate exercise will do no harm. In all these cases a good, substantial, easily-digested diet is required. On the day previous to the operation I order a full dose of castor oil, compound liquorice powder, or Epsom salt, given early in the morning. During the afternoon of the same day, after the patient has had a soap-and-water bath, the abdomen is thoroughly scrubbed, clean clothes are put on, and she goes to bed. In the evening, should there be sleeplessness, some hypnotic should be given, but not opium, as this drug checks both secretion and excretion and tends to nauseate. The morning of the operation the patient is given an enema of soap and water, followed by another bath, and a vaginal douche of bichloride of mercury, 1 to 2000. A carbolized towel is then placed over the abdomen, covered with waxed paper, and retained by a binder.

Our patient now being ready, we will begin the operation. I make the incision in the median line, cutting through skin and fat, with the intention of reaching the linea alba beneath—not always an easy matter, especially when the walls of the belly are not distended. An excellent way to find the linea alba is to pass a grooved director across each rectus muscle, as you see me do here, to the right, and then to the left, and the point of arrest indicates the line. Carefully dissecting through this line, I come to the peritoneum, which lies behind the recti muscles, separated by a cellulo-adipose tissue.

Before opening the peritoneum, hæmorrhage is checked with catch-forceps. I now pick up, with a pair of forceps, the peritoneum, and gently cut through it, taking care not to wound any stray loop of intestine. By inserting two fingers in the opening made, I am enabled, by means of a pair of blunt-pointed scissors, to enlarge the wound to the required extent. I am now in the abdominal cavity and have exposed the wall of the tumor. It is not an ovarian cyst, because it is not nacreous-hued, and besides, it has too great a number of muscular fibres in its walls. It may, however, be an intraligamentary cyst. There is also present some ascitic fluid which must be removed. I think I shall find this to be a tumor covered with the broad ligament.

There are many adhesions, and as I am afraid to break them at once, I shall make the abdominal incision larger so that I may the more readily get at them. These adhesions are upon the transverse colon. None are free, and therefore I must work with extreme care, lest I wound the intestine. There are also other numerous and strong adhesions below, which I try to wipe away with a sponge, but without success.

Now, after working for some time, and with very careful dissection, I have succeeded in enucleating the tumor from the broad ligament. It is an intraligamentary cyst—a variety of tumor that is most difficult to remove. The vessels are now clamped so far as is thought necessary. Other large and most formidable adhesions, extending to—I cannot tell where—make it necessary for me to wash out the cavity of the peritoneum after the operation, because of the escape of clotted blood into the cavity. The tumor is really fastened down by adhesions to the bones of the pelvis behind. As you notice, the patient is greatly emaciated and she has been growing more and more so each day; therefore, without the operation she would have lived but a short time. I do not know yet, as I now take out this tumor, whether it is a uterine or an ovarian tumor. If by any means I open the aorta or vena cava, the patient is done for. Yet I have to run that risk, as I am compelled to work blindly. I am getting along, but it is slow and dangerous work and my heart is in my mouth. I believe now that this is primarily a fibro-cystic tumor, growing from the womb; but the adhesions arising from the posterior bones of the pelvis make its removal especially difficult. It is impossible to break up these adhesions without using force that in this instance would be attended with the greatest danger. At length I have the pedicle separated so that it can be tied. I am very much afraid that this growth is malignant, and, that therefore, the prognosis

is not very good—although I have seen patients quite similar to this, recover without a bad symptom, after just such an operation.

The nerve-strain on me in this operation has been fearful. The fear was that I should wound the intestine or a large bloodvessel. I have lost but one patient on the table, though another died fifteen minutes after the operation.

The particulars of the former case were as follows: I had to go to a town a short distance from Philadelphia, and while there was asked to see a school-mistress who was suffering with vomiting and constipation. She had also two abdominal tumors, and investigation showed that there was a stricture of the rectum. I left directions for the stricture to be dilated, and when I returned, the patient having in the meantime been placed upon tonics and nutrient food, I operated. Unfortunately the etherizer became too much engrossed in my part of the work, as this was the first operation of the kind that he had seen. Both tumors were removed; but the patient died on the table from sheer exhaustion; and, as no one of the other physicians was willing to tell the family of this, it became my sad duty to do so. One of the assisting physicians had diabetes mellitus; the shock to his nervous system was so great that he never fully recovered from it. Every precaution was taken, but without avail. Finally, he tried a change of climate, but this too was a failure, and he died a few months later. This was the sequel to the case. But to return to the accident. The news of it spread through the town like wildfire and everybody wanted to have the minutiæ of it explained to them. I was exceedingly anxious to get home as soon as possible, but found to my horror that there was no regular train until the next day. Fortunately there was an express that passed there in the afternoon, and by telegraphing to headquarters, I got permission to stop this train. I was exceedingly thankful to get away, but, to my discomfiture, when I got on the cars I found that two of the townsmen got on with me, that they knew of the circumstance, and that I had to entertain them with a rehearsal of the details on the way to Philadelphia.

Now to return to the present tumor. There is either a piece left on the sigmoid flexure of the colon, or there is upon that viscus an independent tumor which it is impossible to remove, as it completely encircles the intestine. There is some deep-seated bleeding; and though, as a rule, I would rather tie the vessels than use Paquelin's cautery, I have to use the cautery here. I do not hesitate to touch the bleeding points on the intestines and on the back of the womb. I remove the left ovary and tube also, and the fact of their being separate from the other tumor proves the growth to be fibro-cystic. I now carefully smell the abdominal cavity to learn whether there is any fæcal odor. There is none. If fæcal odor were present, of course it would indicate that there had been an intestinal wound with extravasation. This would necessitate the discovery and closure of the opening. There is still some bleeding going on within the abdominal cavity, and I will attempt to control it by what I am pleased to call the "toilet of the peritoneum," for which purpose I use a clean Davidson's syringe and hot carbolized water. When the water returns perfectly clear I know that the peritoneal cavity is free from blood and clean. Thoroughly draining the abdomen of all fluid, I close the incision; but before doing this I place a clean sponge in Douglas's pouch, another in the sulcus between the bladder and the womb, and a third (large, broad and flat) over the intestines under the wound to catch the blood that may ooze from the cut surfaces.

The sutures have a needle upon each end—which allows them to be passed from within outward. Each needle is inserted about a quarter of an inch away from the edge of the wound, and it is well to include in the sutures all the layers of the parietes—cutaneous, muscular, aponeurotic, and peritoneal. I would lay especial stress on including the muscular layer, although many ovariotomists think that by so doing abscesses in the recti muscles are apt to follow in the suture-tracks. But it seems to me that it is better to run the risk of a stitch-abscess than the more serious and grave one of ventral hernia.

Having inserted all the sutures, I remove the sponges from the abdomen, and am rejoiced to find that there is scarcely any blood on them. This tells me that there is but little bleeding from the sutures or from the abdominal cavity itself. I now count my instruments and sponges, and find the number correct, and then close the incision without having to use a drainage-tube.

My method for closing the wound is by grasping in one hand all the sutures on my side, while my assistant does the same upon the opposite side; thus the edges of the wound are brought firmly together, and at the same time all air is expelled from the abdominal cavity. Each suture is then tied with the surgeon's knot. The entire wound being closed, the ends of the sutures are gathered together and cut off several inches from the knots. The wound is dressed with the usual antiseptic precautions: First, it is thoroughly cleansed and dried; next iodoform is freely sprinkled over the surface of the abdomen, and particularly into the umbilicus; then several layers of carbolized gauze are placed over the wound, and over the gauze adhesive strips of rubber plaster are fastened; last of all comes a wad of cotton-wool which has been thoroughly baked in order to destroy all germs. This is held in place by a flannel binder.

I shall now give the patient a suppository of opium, not only to soothe the pain, but especially as a nerve stimulant; because her peritoneal cavity was open for more than an hour and there were numerous adhesions, perhaps later she may require another suppository.

The after-treatment will consist in keeping the patient on her back, and without food for twenty-four hours. Hot cans will be applied to the body, care being taken that they do not come in too close contact with the skin, as the burns which they make are unusually severe. She will be allowed to see no one but the physicians and the nurse for several days, as absolute quietness must be observed.

Should obstinate vomiting occur, ice will be given or sinapisms applied to the epigastrium. If there is much flatulence, it will be relieved by inserting a flexible catheter high up into the rectum, or by enemata of turpentine, soap and water.

As a rule, it is necessary to catheterize for a day or so after the operation, but it should be avoided if possible,

as the too frequent use of the instrument is likely to cause an irritable bladder that is slow to respond to treatment.

On the second day we will give half an ounce of milk every two hours, gradually increasing the quantity as her condition demands it.

If her temperature should reach 101° or over, ice will be applied to the head, the body sponged, a saline cathartic given, or some antipyretic administered.

On the fourth or the fifth day the bowels will be freely opened with castor oil, or compound licorice powder. If these fail to act, they will be supplemented by an enema.

In from seven to nine days the dressing will be ready to be removed and the stitches will be taken out.

PROGNOSIS IN PULMONARY TUBERCULOSIS,

Based upon an Analysis of Five Hundred and Fifteen Cases.[1]

BY KARL VON RUCK, B.S., M.D.,

DIRECTOR OF THE SANITARIUM FOR DISEASES OF THE LUNGS AND THROAT, ASHEVILLE, N. C.; MEMBER OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION, THE AMERICAN MEDICAL ASSOCIATION, ETC.

IF I should state that of 515 cases of pulmonary tuberculosis 59 recovered and 65 showed material and lasting improvement, and that the percentage of recoveries was eleven and a fraction, such statement would aid but little in the prognosis of a given case, and also would be unreliable as to the necessary mortality of cases, unless all of them came under treatment and observation at the same stage of the disease and remained under the same conditions until the outcome was determined. Should I endeavor to base a prognosis upon the first 181 cases of my series, in which there were but 3 recoveries, I might well doubt my diagnoses, and take it for granted that in these 3 cases my senses deceived me, and that the disease was always fatal.

Statistics based upon the diagnosis of tuberculosis previously to 1883, or upon cases in which bacilli were not invariably demonstrated, would, in all probability, include some cases of non-bacillary disease. My deductions are based upon cases in which the microscopical diagnosis was clear, which have been under my own observation, and of which I have not only the histories and records while under my care, but have also been able to ascertain the course of the disease up to the date of my inquiry, by direct and indirect communications with patients and their friends, or their physicians. I take this opportunity to express my thanks to the physicians to whom I frequently appealed for careful replies, without which the number of cases available for classification would be much smaller. I hope that the vast amount of labor involved in correspondence and detailed inquiries may be justified by a more ready appreciation of the various points which bear upon prognosis directly or indirectly, and perhaps by the adoption of means, or avoidance of influences, which appear to affect the course of the disease.

It may be well to explain here my meaning when speaking of *improved* or *recovered* cases. Under the former I include all patients in whom general and local improvement lasted for a number of months, the temperature, as a rule, not exceeding 100° F.; who gained in flesh and strength and were able to resume their vocations; in whom cough and expectoration were materially diminished, but still present at the time of their discharge, and who, as far as ascertainable, still show tubercle bacilli in the sputum. (In some of these cases sputum examinations have not been made for several years; some sent me specimens by mail; others had examinations made at home.)

As *recovered* cases, I report those in which all local and general symptoms have disappeared, no active symptoms having been present for six months or more; cough and expectoration having nearly or quite ceased, with continued absence of bacilli in the sputum, if slight expectoration still exist. A number of the improved cases could have been included among the recovered were it not for the bacilli which still appear in the slight expectoration.

The following table shows the influence of age and the general mortality of my cases. Among the fatal cases I have also included patients who are still alive, but who are growing worse, and in whom the termination will probably be fatal:

Age.	Total number of cases.	Number that have died or are growing worse.	Per cent.	Improved and are still doing well.	Per cent.	Recovered.	Per cent.
5 to 15	5	5	100	0		0	
15 " 20	24	22	91.6	1	4.2	1	4.2
20 " 30	186	153	82.2	16	8.6	17	10.5
30 " 40	216	152	70.4	39	18.0	25	12.0[1]
40 " 50	67	46	68.6	7	10.4	14	20.8
50 " 60	16	12	75.0	2	12.5	2	12.5[1]
60 " 70	1	1	100	0		0	
Total.	515	391	76	65	12.5	59	11.5

The influence of age.—Of the 391 cases who died or have become hopelessly advanced in the disease, there are 223, or 57 per cent., who, at one time, while under my care, showed somewhat encouraging improvement; 67 of these to such an extent that permanent arrest seemed probable. In these 67 cases (38 per cent.) the relapses were, with few exceptions, due to preventable causes—as a rule, to

[1] Read before the Buncombe County Medical Society, Asheville, N. C., July 7, 1890.

[1] One of the recovered cases that died of other disease.

the too early abandonment of climatic and general treatment, obstinately continued over-exertion, or to imprudent exposures. In 8 cases the relapse was clearly referable to epidemic influenza. The latter disease also caused serious relapses in several cases in which the disease was nearly arrested. Four cases that I had considered as cured I have excluded from my report of recovered cases, as I am unable to determine the exact nature of the lung disease which accompanied the influenza, and which continued until death, the patient not being under my care at the time, and microscopical examinations of the sputum not having been made by the attending physicians.

The apparent influence of age upon prognosis is shown by the table to be favorable in proportion to the number of years up to fifty, after which the effects of advancing age seem to influence the prognosis somewhat adversely. The number below twenty years and above fifty is, however, so small that no conclusions are really justifiable.

The influence of sex.—Of the 515 cases, 290 were males, of whom 212, or 73.2 per cent., died or have grown worse; 38, or 13 per cent., improved; and 40, or 13.8 per cent., recovered. Of females, there were 225, of whom 179, or 79.6 per cent., died or have grown worse; 27, or 12 per cent., improved; and 19, or 8.5 per cent., recovered. If, however, of female patients we include only those between the ages of fifteen and forty years, we find that the dead and hopeless cases amount to 85.3 per cent., with improvement in 9 per cent., and recovery in 6 per cent. Furthermore, I find that the climacteric period furnished a proportionally larger number of female patients, as compared with men of the same age. Of the 67 patients, between the ages of forty and fifty years, the number of females was 41, or 61 per cent., whereas male patients predominate during every other period, except that between ten and twenty years, where females again are in the proportion of 18 to 12, or 68 per cent. This may be coincidence, especially with some cases that were treated at my institution, or at a distance from their home, yet it seems reasonable that the two great epochs, puberty and the climacteric, especially if complications incident to these periods exist, may lead to nutritive disturbances, such as chlorosis and anæmia, and thereby predispose the individual more strongly to infection.

Whereas all the female patients between the ages of ten and twenty years, died or became hopeless cases, the 41 cases, between forty and fifty years, furnish the largest percentage of recoveries, being 10 recoveries, or 25 per cent., against 4 recoveries, or 15.4 per cent., in males of the same age. In 33 of these 41 female patients, menstruation had permanently ceased when they came under my care.

I have frequently noticed that female patients are apt to lose ground during the menstrual week, and this often in the absence of any special disturbance of their menstrual function. Fever if absent is apt to return, and if fever has been present it is several degrees higher, for a day or two, immediately preceding the menstrual flow. If the period is entirely missed or is delayed the increased temperature has often been observed to continue throughout the time corresponding to the menstrual week. In addition, increased cough, diminished appetite, and digestive disturbances, are frequent, and a loss of several pounds in weight has been noticed in a number of such cases who had been gaining. When such disturbances are repeated monthly they interfere, sometimes quite seriously, with the favorable progress of a case, and must to some extent influence the prognosis.

The occurrence of pregnancy, during any stage of pulmonary tuberculosis, renders the prognosis serious, even in an otherwise favorable case. Of my 225 cases, 13 became pregnant during the earlier stage of the disease; all went to term and were delivered of apparently healthy children; in all active symptoms returned or increased within nine weeks after delivery; in 4 marked temporary improvement again occurred, 12 died, and 1, otherwise a very favorable case, recovered.

It would, therefore, appear that in the female the prognosis is less favorable if her menstrual function be accompanied by the disturbances that are mentioned above, and more favorable if the climacteric period has been passed.

The influence of heredity.—There are few practising physicians who will be convinced by the laboratory student that hereditary influences have nothing to do with the etiology of tuberculosis and that the acquirement of the disease is accidental. I not only feel absolutely convinced that heredity is an indirect factor in the acquirement of tubercular disease, but it appears also from my records that *the prognosis in such cases is much less favorable.*

No one to-day maintains that heredity means the transmission of the morbific agent which causes the disease. Those who believe that heredity is a factor claim, on clinical grounds, that the subjects of such heredity furnish a larger proportion of cases of pulmonary tuberculosis than those with no inherited tendency, and that had heredity no influence in causing the disease, the number of cases should be the same in those who have and those who have not a consumptive family history.

Among 100 interrogations from patients with phthisis (casually made as I had opportunity and in a locality where phthisis is prevalent) I received 88 negative answers, as to the disease having been present in their respective families. Granting, how-

ever, that such a history could be shown in 18 per cent. of the entire population, why is it that more than twice this percentage of tubercular patients show such a history? It is generally accepted that parents transmit physical and often mental peculiarities to their children, why not believe that diseased, weakly and constitutionally depraved individuals should produce weak offspring? We require no predisposition of tissues, only a generally depressed and weak constitution, which causes the organism to be deficient in its nutritive processes, in its force-producing, injury-resisting, and repairing powers, as compared with individuals who have no such heritage.

Observing physicians believe that such people have little power to resist, and readily become victims to tubercular infection. This would be still more probable if such persons also inherited, or acquired by faulty development, a phthisical thorax, a small heart, a tendency to glandular enlargement, etc., all of which would lead to nutritive disturbances in general and of the lungs in particular. The non-resistance of such persons is only relative. In the cases of acute miliary tuberculosis, or acute phthisis, in which, at least after infection has taken place, non-resistance to the progress of the disease is apparent. In other people the resisting power may be more or less, according to their individuality; all being influenced for the time being by the various conditions of general health, and the intactness of the part in which the infecting germs lodge. I do not believe that any human being possesses an absolute immunity from infection and I have no doubt that if enough of the tubercle bacilli find entrance into the organism, no matter by what avenue, infection will result. The behavior of the infected organism toward the progress of the disease, and in repairing the damage done, may, however, be very different in the constitutionally strong than in those who are predisposed in the sense that I have explained. Speaking for myself as a strong believer in hereditary predisposition, and in a larger sense than the term is generally applied, I would be most unwilling to inhale even the smallest number of tubercle bacilli, although I am in no sense predisposed to infection.

According to my understanding, the predisposition by heredity need not be the result of phthisical disease of the ancestors, which I have termed *direct hereditary predisposition.* Want of resisting power in the offspring may be the result of a variety of conditions, under which the parents produced a child that easily succumbs to various causes: but if it lives long enough and if circumstances are favorable, it falls a victim to tubercular infection. This I have termed *indirect hereditary predisposition.*

In my 515 cases the question of heredity was fully answered and recorded 501 times—in 14 cases the patients knew so little of their family history that they could not be satisfactorily classified.

Direct hereditary predisposition (phthisical family history) was shown to have existed 202 times as follows:

From the father's side alone in	51	cases.
From the mother's side alone in	80	"
From both parents in	11	"
From father and grandfather alone in	12	"
From mother and grandmother alone in	20	"
From both parents and both grandparents in	3	"
From grandfather alone (skipped one generation) in	8	"
From grandmother alone (skipped one generation) in	17	"

Total, 202 cases, or 39.2 per cent. of all.

As may be seen, the mother and grandmother seemed to transmit a predisposition most frequently. The possibility of this was present in 131 and is evident in 117 cases, whereas on the part of father and grandfather it was possible in 85 and evident in only 71 cases.

Indirect hereditary predisposition could be shown in 217 cases, or 42.3 per cent., as follows:

(*a*) Ninety-two cases were children, the sixth or later in large families, often born in rapid succession, none of the older children having acquired the disease; but in 26 cases younger brothers or sisters were also suffering from or had died of phthisis. The history of these patients was almost without exception that they had been less strong and robust than the older children, or had been sick from various causes a great part of their lives.

(*b*) Twenty-two cases were either one of twins, or the mother had given birth within a year previously to another child. In these cases again, the tubercular patient had nearly always been the weaker one, and delicate from childhood. In two instances the other twin had already died of phthisis.

(*c*) In 59 cases one or both parents were suffering from impaired general health at the time of conception or during pregnancy—chronic diarrhœa, chronic dyspepsia, cancer, syphilis, disease of the genito-urinary organs, uterine disease, etc. There were also histories of sickness or death of brothers or sisters from meningitis (tubercular?), chronic disease of joints, rickets, spinal disease, scrofula, etc. In 14 cases death in the family from measles and whooping-cough was stated to have occurred, and 28 patients gave a history of scrofula in childhood. In 19 cases brothers or sisters were suffering from or had died of phthisis.

(*d*) Forty-four cases gave as part of their histories, that one or both parents were suffering from severe nervous disease previously to the birth of the

patient, including insanity, paralysis, locomotor ataxia, and epilepsy. In 9 instances brothers or sisters were or had been suffering from epilepsy or from chorea: in 8, brothers or sisters were suffering or had died from phthisis.

In 78 of these 217 cases the so-called phthisical habitus was noted, although no phthisical history was present, against 136 in the 202 cases in which direct hereditary predisposition was shown.

Considering, now, these 217 cases, their percentage and the circumstances under which the patients were born, is it surprising that such persons have acquired a depraved constitution, or a predisposition to fall more readily victims to disease?

Is it not reasonable to suppose that the minimum amount of infecting material which in such cases would produce phthisis, would be resisted and overcome by stronger persons coming of a better stock?

There remain now 96 cases in which the family history was good, both as to direct and to indirect predisposition, and in which the health was, as a rule, good from infancy. In these we can believe that either they received a sufficiently large dose of infecting material, that such infecting material was of unusual virulency, to which their relative good resisting-power was inadequate, or that they had become temporarily predisposed. In 56 cases the health was said to be good to the time of the development of phthisis: in 4 the disease followed typhoid fever; in 3 croupous pneumonia: in 8 catarrhal pneumonia; in 5 childbirth: in 1 puerperal fever: in 3 peritonitis: in 1 acute pleurisy: and in 1 measles. The others, as most tubercular patients do, ascribed as a cause "catching cold," by which, perhaps, we should understand "catching tubercular infection."

To show the influence on prognosis of direct, indirect, or no hereditary predisposition, we find from an analysis of my cases that the prognosis does not materially differ, whether direct or indirect predisposition existed. But I was much surprised to find that when hereditary predisposition was absent, six times as many recovered. I have gone over these cases again and again to prove that no error is present; each time with the same result. I then divided the cases into groups according to the years of their occurrence, again with practically the same result.

Table showing the Influence of Heredity upon Prognosis.

Grouped under.	Number of Cases.	Recoveries.	Per Cent.
I. Direct hereditary predisposition (family history of phthisis),	202	9	4.5
II. Indirect hereditary predisposition, *a*	92	6	6.5
" " " *b*	22	1	4.5
" " " *c*	59	3	5
" " " *d*	44	3	7
III. No hereditary predisposition	96	37	37.6

In view of this extraordinary showing, it is very desirable that other observers consult their records, or make proper inquiry hereafter, and publish their results. This will show whether my results are correct or incorrect. For such inquiries a systematically arranged series of questions is absolutely necessary. It is essential that the patient should understand that a full statement of the facts, even if it is necessary to make inquiry of friends, has a most important bearing on their individual case.

The influence of the stage of the disease.—Of course the earlier a case, which is susceptible of improvement, comes under proper treatment and management, the better will be the outlook, and no statistical evidence is required to prove this self-evident proposition. Of the 515 cases, 81 were classed as in an early stage and 434 in an advanced stage. Of the 81 early cases, 11 remained under treatment for so short a time that no material change could be expected; 34, or 55.5 per cent., showed improvement and then relapsed, as a rule from causes within their control—all these have since grown hopeless or died; 17 cases, or 21 per cent., are improved, and 20 cases, or 24 per cent., have recovered. Of the 434 advanced cases the disease progressed without material improvement in 125, or 29 per cent.; improvement more or less temporary occurred in 189, or 43.5 per cent.—all relapsed, many from preventable causes, and have grown worse or have died. Marked improvement with prospective arrest of the disease occurred in 33, or 7½ per cent.; all these have relapsed, often from causes within their control, and have grown worse or died; 48, or 11 per cent., of the cases still remain much improved, and 39, or 9 per cent., have recovered. From a scrutiny of these results it is apparent that had an ideal course been pursued in all cases, many more recoveries would have resulted. The fact is, that such a course was pursued only exceptionally. Taking the improved and recovered cases together we have in the early stage 45 per cent. and in the advanced stages 20 per cent. Of the 515 cases there were three females and one male in whom, although they came under observation early, the disease followed a rapidly fatal course—all deaths occurred within four months. Every effort seemed unavailing to cause even a temporary halt. Aside from the slower course of these cases they differed clinically from acute miliary tuberculosis, in that pulmonary symptoms were more prominent, and the stage of breaking-down and excavation was reached. Physical examination showed the evidence of diffused bronchitis, with many small areas where the respiratory murmur resembled the bronchial. Very little change in the percussion-note was manifest.

In one case the infection could be traced to a cut upon the finger of the left hand, which became

inflamed, as did the lymphatics of the arm, and was soon followed by a glandular swelling in the axilla. The general health began to fail after this and before any attention was attracted to the lungs. The patient and her friends, I was told, had obstinately refused to have the swelling incised, though the tubercular character of this was not suspected. The case came to me with this history and a cough, supposed to be bronchitis, which had existed for three months. The slightly fluctuating, enlarged gland was still noticeable. The patient died ten days later.

Although I could find no source for infection through the blood in the other three cases, I cannot but believe that it must have existed. They all pursued almost an identical course, and the diffused tubercular deposits with numerous broncho-pneumonic centres throughout both lungs were characteristic of all.

The extent of lung tissue involved in any stage necessarily influences prognosis. Under proper management further involvement of the healthy tissue of other lobes, and especially of the opposite lung, as long as general infection has not occurred, can, as a rule, be prevented. The bacilli having no independent motion must probably be first expectorated to reach with the inspired air healthy parts of the lung, though further infection may also occur by the gravitation of the secretions. For this reason it is important that an already infected case does not inhale more bacilli, and one of the first conditions of proper management is so to take care of the excretions, and especially of the expectoration, that the danger from this source may be reduced to a minimum. The tendency to extensive destructive processes without connective-tissue repair, which determines the formation of cavities, and with the latter an increased liability to severe arterial hæmorrhages, and to long-continued suppuration from the walls, with the attending danger of septic absorption and amyloid degeneration of other organs, influences the prognosis very much. But the mere fact that a cavity exists does not necessarily cloud the prognosis, if the cavity is of moderate size and located favorably. It is then of more importance to determine the presence of still active disease and its extent, and whether the cavity is secreting and enlarging, or is dry with a tendency to cicatrize and to become obliterated or lined with smooth, fibrous wall. If there is cicatrization the patient has passed through the critical period of softening and suppuration, and he may continue upon a course of uninterrupted improvement. Large cavities in the lower portions of the upper lobe, and those in the lower lobes, or those that for any reason have an imperfect outlet, are apt to remain inflamed, to secrete profusely, and to discharge irregularly. Such cavities frequently continue to enlarge by progressive breaking-down of their walls and to cause exhaustion, particularly if there is much fever.

The influence of the digestive organs.—As long as a fair degree of digestive power and of assimilation of food can be maintained, and if the disease is not hopelessly advanced, we should not despair. On the other hand, it matters little how how many encouraging signs we may see in a case: unless we can keep up the nutrition our efforts must ultimately prove fruitless. Many cases acquire gastric and intestinal disturbances by the injudicious use of alcoholics and improper food, and by the use of drugs and patent medicines, especially those which contain opiates. There is also a tendency to sympathetic functional disturbances, especially of the stomach. All such disturbances can, as a rule, be controlled by a proper regimen. If, however, structural disease of the digestive organs exists, be it due to the abuse of alcohol, or to long-continued gastric catarrh from other causes; if we have reason to suspect amyloid disease of the vessels of the intestines, of the liver or of the spleen; if we have fatty liver, or tubercular disease of the biliary passages or of the intestine, we cannot hope to nourish our patient thoroughly. In several cases in which I had the opportunity of seeing the results of autopsies upon patients who had followed the so-called "whiskey cure," I was not surprised at my failure to improve the nutrition. There was atrophy of the gastric glands in one case, with dilatation of the pylorus. In another case the stomach was in a state of severe catarrhal inflammation.

Of functional disturbances none has resisted efforts for permanent relief so obstinately as gastric and intestinal accumulations of gas. In mild cases I have succeeded well enough with diet and the administration of salol; but I have had a number of cases in which all measures failed, and the distress occasioned, as well as the interference with the absorption of food, seemed to hasten materially the downward course of the patients. I could not believe that the gas was due to fermentation, but rather attributed it to non-absorption by the intestinal mucous membrane. Occasional watery stools were also present and some failure of the right side of the heart, with variable increase in the size of the liver. The distress was least after maintaining the recumbent position for a number of hours, causing me to suspect that the abdominal viscera were in a state of passive congestion, which interfered with absorption. In neither of these cases was there any improvement.

Purely functional disturbances of the digestive organs frequently accompany the initial stage of the disease, and simulating dyspepsia they divert the attention from the real cause. Much time may be lost by treating the dyspepsia alone, and harm may

be done by restricting the diet, frequently to artificial food-products, which are poor substitutes at all times. Such conditions if improperly managed cause rapid advance of the lung affection, and require forced feeding with milk, eggs, light meats, and especially with vegetables, in small quantities frequently repeated, to be increased by fats after some improvement has been made. Among medicinal agents creasote, bitter tonics, and wines have seemed beneficial.

There are cases that seem to have no disturbance of their digestive organs and have a good appetite, and yet gain nothing in weight or even continue to lose. Upon inquiry it is found that these cases have daily two to three large evacuations. In such cases if the nutrition is not improved by giving less food and by administering it in frequently repeated, small quantities, the prognosis is unfavorable.

Slight peptonuria, demonstrated by Ehrlich's method, has been noted in a number of cases of recent date, no tests having been made in my earlier cases; profuse and continued peptonuria was found only in rapidly progressing and ultimately fatal cases.

Absolute increase in the amount of urates and uric acid I have frequently seen. It is probably due to diminished oxygenation by obstruction and increased venous tension, diminished respiratory surface, and diminution of red corpuscles. Such patients for the time lost flesh. If this condition could not be relieved by inhalations of oxygen in large quantities, and if it persisted, it affected the prognosis unfavorably.

The influence of fever, cough, and expectoration.—Fever, cough, and expectoration are common to all cases of pulmonary tuberculosis. It is their intensity and persistency rather than their presence which influence prognosis. In considering them we should also consider the stage of the disease, the previous management, and the deportment of the patient. The fever, in a case under proper management, and when indiscretions of the patient are excluded, pretty clearly reflects by its amount, the activity and extent of pathological processes at the seat of the disease, and reaches, as a rule, its maximum during the stage of softening, absorption, and excavation. If during that period it is moderate, if areas of softening are small and circumscribed, and if we have one lung or a considerable portion of both lungs unaffected, we need not despair. It is a nice question of judgment to estimate the probable duration of this stage. If the patient's nutrition is still fairly good, and if we succeed in preventing serious loss of flesh, or, better still, if he should show a slight gain, we have good reason to believe that the process will remain circumscribed, that tissue-repair will probably take place, or that the cavities will be small and speedily made, and that the patient will pass safely through this stage. After this, improvement will follow. Such has been my experience with the cases I am considering. When large areas are involved, when the temperature rises very high and becomes several degrees subnormal, once, and occasionally twice in twenty four hours, and if the rise is accompanied with a distinct chill, it is not often that the patient's nutrition can be kept up, and, as a rule, the stage is indefinitely prolonged, and leads to a fatal result. Afebrile periods usually correspond to periods of improvement.

The cough bears a certain relation to the fever, and unless due to non-specific bronchitis is not often troublesome in cases in which the temperature is below 100° F., if over-exertion and fatigue are avoided.

The cases in which the bronchial mucous membrane was extensively involved—the so-called broncho-pneumonias—usually ran their course with higher temperatures, and in these the cough was most severe and exhausting, yielding to nothing short of opiates. The intensity of the cough, its interference with rest, and the effects of opiates on the patient, certainly influenced the prognosis, which appeared, however, always less favorable in the broncho-pneumonic form of the disease. Cough due to catarrhal states of the upper air-passages, or to the symptomatic catarrhal bronchitis, yielded, as a rule, to proper local treatment by inhalations, etc., and did not affect the prognosis.

The quantity and quality of expectoration stand in intimate relation to the stage of the disease. Bloody sputa in the early stage betoken inflammatory changes and extensions; later the sputum comes from ulcerated, inflamed, or congested cavities, especially when the patient has over-exerted himself. The color of the expectorated blood depends upon the time it remained upon the respiratory surfaces; it is, therefore, an aid to diagnosis, but only indirectly of prognostic significance. Purely purulent sputa is rare in phthisis, and belongs to abscess or empyema. A muco-purulent character is the rule, and it is greatest in quantity during the stage of softening and excavation. Cheesy particles in the sputum come from recent cavities; sand-like or calcareous concretions from old inspissated, purulent, or cheesy deposits, or degenerated bronchial glands. They have no special prognostic significence, except that their presence in the lung is likely to cause suppuration until the particles are expelled.

It has been thought that the number and form of the tubercle bacilli in the expectoration could be made a basis for estimating the intensity of the pathological process and for prognosis. I, too, have endeavored to draw some inferences, but offer my conclusions

with some diffidence, and shall be glad to be corrected if I am wrong. It has seemed to me that I am not mistaken. I realize, of course, that the number of bacilli varies greatly, as we select for examination a cheesy particle or one of only muco-pus. To avoid this source of error I have used various expedients which I need not mention in detail, the object being to get a uniform specimen, and I find that I can obtain a pretty equal distribution of the bacilli upon the prepared cover-glasses. If now, repeated examinations showed a steady decrease in the number of the bacilli until finally but a few and occasionally none were found, and especially if the bacilli were very small and thin, and if the peculiar effect in staining, believed to be due to the presence of spores, was absent or but rarely noted, the specimen came from a case that was improving in general health, and in the local conditions, in every instance. In cases running an unfavorable or indifferent course no such results were observed.

The influence of the pulse.—Many of my predisposed cases, in fact almost all of them, showed a much increased pulse-rate, as is common in phthisis, even in the absence of fever, and when the latter was present the frequency of the pulse was usually out of proportion to the temperature. A congenitally small heart, which was frequently associated, does not show compensatory hypertrophy when obstruction exists in the lesser circulation, if fever and other nutritive disturbances are present. Even a heart of normal size soon shows the results of such injurious conditions by a less perfectly filled radial artery and a more frequent pulse-rate. The auspicious cases had a comparatively slow pulse, and when fever was absent the pulse-rate approached the normal. This was observed in all my greatly improved and recovered cases.

The influence of concomitant tubercular disease in the upper air-passages.—In 81 cases, in the early stage of phthisis, tubercular laryngitis was present in 5 only. In the 434 advanced cases it was noted 111 times. I propose to make these cases a special study in the future, especially with a view to show the effects of various modes of treatment according to the extent, location, and stage of the lung affection when the disease of the larynx made its appearance. I may say here that in the majority of cases no results were obtainable from treatment as long as the lung disease was progressive, but in 2 cases in an early stage, and in 10 in an advanced stage, complete cicatrization occurred. These 12 cases still belong to the improved or recovered cases. No case recovered in which the ulcerative and destructive processes were extensive. The epiglottis was seriously involved in 19 cases, none of which recovered. The painful deglutition seriously interfered with nutrition, and the severe paroxysms of cough, too, tended to exhaust the patients, who were nearly all in the last stages. In only 1 case was the pharynx the seat of tubercular disease, and this case also had a small tubercular ulcer of the tongue, with, however, but slight pulmonary deposit; the patient did not improve, but is still alive.

The influence of pulmonary hæmorrhage.—I notice a material difference between the frequency of pulmonary hæmorrhage in my patients in private practice and in those treated in my institution. In the former it occurred in about one-third of all cases; in the latter, in less than one per cent. Besides the anatomical changes which make hæmorrhage possible, over-exertion nearly always preceded it in the cases in private practice and in every case in my institution. In the early stages the hæmorrhage is moderate, results from inflammatory changes, and is simply a diapedesis. In the latter stages moderate hæmorrhage comes from granulating cavities; when severe, it is arterial, and due to the rupture of sacculated or degenerated and still pervious vessels in the cavities. In estimating the effect upon the future course of the disease we must consider the presence or absence of the various other factors which enter into the prognosis. Even a slight hæmorrhage is at least a temporary hindrance to favorable progress, excluding the exceptional cases in which cough and other symptoms are relieved by the local bleeding of a congested area. But tubercular patients can ill afford the loss of blood even in small quantities. The necessary confinement and the loss of blood itself must certainly, for the time being, check further improvement. If treated by all sorts of mineral and vegetable astringents, ergot, etc., given by the mouth, and if the patient is kept on a diet of ice pills and, perhaps, a few spoonfuls of milk or broth, the loss in nutrition is a further hindrance. Profuse hæmorrhage, especially if repeated, leads to rapid exhaustion, and may terminate a case abruptly by suffocation.

The effect of pleurisy.—Pleurisy, if dry and circumscribed, did not influence the prognosis. Indeed, pleurisy may be conservative by causing thickening and adhesive inflammation over cavities which might otherwise perforate and lead to pneumothorax, a complication which is the beginning of the end. Simple pleurisy, with serous effusion occurred in 5 of my cases, and did not seem to exert any material influence upon the subsequent course of the disease, except that the patients lost flesh and strength during their confinement. Tubercular pleurisy, as a complication, has been recovered from in but 2 of my cases; in these the effusion subsequently became purulent, and required resection of a rib. For a time after the operation the patients improved remarkably, but were then lost from observation, and have since died.

The influence of nasal stenosis. — In 483, or 90 per cent. of cases, catarrhal affections of the nose and throat were present, and there was evidence that they had preceded the lung disease in the great majority of cases. In 221 cases the catarrh was associated with nasal obstruction from turbinated hypertrophies, polypoid growths, septal thickenings, deviations and excrescences that markedly interfered with free respiration through the nose, especially at night; but often during the day also, the patients were obliged to breathe with the mouth open when taking exercise. To what extent these conditions may have favored the deep inhalation of infecting bacilli I cannot here consider, but I am sure that nasal stenosis frequently interfered with improvement, which in many cases occurred only after the obstruction had been removed by proper treatment.

The influence of rectal fistula and peri-rectal abscesses.—Rectal fistula was noted in 27 cases. In 3 cases in the early stage I operated successfully, and 2 of these finally recovered; 24 cases were in an advanced stage of the disease; 1 of these recovered and was subsequently operated on at home. In neither of the other cases was an operation attempted, nor did the fistulæ seem to exert any influence on the disease, though they were an annoyance, frequently became inflamed, and discharged continuously. Small peri-rectal abscesses I have observed more frequently, but have not always kept a record of their occurrence. In all but 4 cases they were immediately incised when discovered, and healed kindly. In the 4 cases in which incision was delayed by the patient neglecting to call attention to the swelling, fistula resulted. In several of such cases tubercle bacilli were found in the pus.

In conclusion, the personal hygiene and the healthful environments of patients; their steadfastness of purpose and determination; their own proper estimation of the importance of early measures and of implicit compliance with advice; their willingness to make necessary sacrifices, and also the painstaking management of the physician in charge, and his ability to prevent even slight complications, all exert influences which are none the less real or important because their effects are an unknown quantity.

SELECTED SURGICAL CASES.[1]

By DONALD MACLEAN, M.D.,
of Detroit, Mich.

The following cases have been selected for presentation in the hope that, whether regarded from a theoretical or a practical standpoint, they may be deemed worthy of consideration. They will be detailed with as much brevity as is consistent with intelligibility.

I desire to call attention here to the value of subcutaneous section of the anterior annular ligament of the wrist, and to a similar operation in the neighborhood of the ankle-joint, especially for the relief of the condition known as compound ganglion. In a communication presented to the American Surgical Association in 1885, I invited attention to this subject, and reported a number of characteristic cases occurring in my own experience. Since that paper was published I have had numerous opportunities to test the value of this method; moreover, I have come to believe that this simple procedure is of great value in other conditions besides the one referred to.

In rapid and violent inflammations involving the tissues of the palm, or those of the dorsum of the foot, whether from a poisoned wound or other cause, the subcutaneous division of the anterior annular ligament will not only afford immediate relief to the patient's suffering, but will do much toward giving the constricted and inflamed tissues an opportunity to recover their normal equilibrium; somewhat in the same way, and on the same principle, that iridectomy affords relief and benefit in certain diseases of the eye.

From a number of characteristic cases I have chosen the two following for the purpose of illustrating this subject:

Case I.—On November 20, 1887, I was called by telegram to Springport, Jackson County, Michigan, for the purpose of amputating the right hand of Mrs. W., aged thirty-five years. I found the patient suffering intensely from extensive suppuration of all the tissues of the right palm, and with corresponding constitutional irritation and alarming depression.

She was tired of suffering, and willing to submit to anything for relief. On inquiry I found that for at least eight years she had been troubled with a large compound ganglion of the palm. Various methods of treatment had been tried without effect, and a few weeks previously to my visit a seton had been used. Suppuration supervened, and when I saw her the condition was in every respect most critical.

I determined to try one more expedient before sacrificing the hand. Accordingly, chloroform having been administered, I made a thorough division of the anterior annular ligament, from which on recovering consciousness the patient declared herself materially relieved. I did not see this patient afterward, but her medical attendant, Dr. Winslow, informed me that the relief proved permanent, and that, notwithstanding a severe continued fever, with which she was attacked a few weeks after my visit, she made a good recovery, with a perfect, or nearly perfect hand.

Case II.—This case will serve to demonstrate the

[1] Read before the Surgical Section of the Michigan State Medical Society, at Grand Rapids, June 19, 1890.

value of the operation in a different and, no doubt, more common class of cases:

Mr. A. H., Mount Pleasant, Michigan, aged forty-two years, married, was admitted to the Hospital of the University of Michigan November 14, 1888.

While at work in a saw-mill, November 3d, he bruised the fingers of his right hand in the machinery. The little finger was the only one much injured, and that not so seriously as to stop his work. But he thinks that, on November 7th, he sprained the right hand and wrist. It immediately began to swell, and to give him great pain. The swelling and intense pain continued up to the time of his admission. His family physician used poultices and other applications, but with no relief. When admitted, the right hand and forearm were enormously swollen, and the patient was suffering intensely. Dr. Abbott immediately opened the hand and fingers by free incisions, and evacuated a large amount of pus and dark, decomposing blood. The hand and arm were then placed in hot water, and the patient experienced some relief. On November 15th, he presented himself at the clinic. The good effects of Dr. Abbott's highly judicious treatment had disappeared, and the patient was again in great agony.

Here was a case in which a slight bruise of the fingers had led to the involvement of the entire hand and forearm in a severe inflammatory process, and it was very apparent that unless arrested this process would soon lead to destruction of the parts by gangrene.

Without using an anæsthetic the anterior ligament was at once divided with a fine, sharp-pointed tenotome. Slight hæmorrhage followed the operation, and the patient experienced immediate relief.

November 16. The hand was dressed in bichloride gauze, and a firm bandage applied.

20th. Bandage has been applied, wet, every day, and the patient is improving rapidly. Temperature normal now, while it has been up to 105° during most of the past week.

22d. Glycerin and iodine were painted over the hand and arm to promote absorption. No fever.

24th. Swelling greatly reduced, and pain almost gone. Movement returning gradually. Discharged.

December 20. A letter just received from the patient states that he has resumed work with complete use of his hand. There is slight stiffness of the fingers, which is rapidly disappearing.

REMARKS.—The first hint of this practice undoubtedly came from Syme, the author and source of many advances in practical surgery. Syme, however, operated by free incision, and I trust that I am not presumptuous in claiming, in this instance, an improvement upon his practice by substituting the subcutaneous for the more heroic and certainly more dangerous open method.

The following case of neuroma of the median nerve has seemed to me to possess more than one point of interest:

CASE III.—Mrs. C., aged thirty-one years. Introduced to me by my friend and former pupil, Dr. Frazer, of Sarnia, Ontario.

Patient had had a tumor in her right forearm nearly all her life. Ten years ago it became very painful, and led her to seek medical advice. Removal was suggested, but this she declined and came to Michigan, preferring to place her case in the hands of a quack, who undertook to eradicate the growth by the application of caustic plasters. This treatment resulted in her confinement to bed for a period of eight months, during which her sufferings were very severe, and at the end of that time her tumor was somewhat larger, and a great deal more painful.

On May 8, 1890, I saw the patient and examined the tumor, which was situated about four inches above the wrist, on the right forearm, and was evidently connected with the median nerve. It was impossible to manipulate it much owing to its extreme tenderness. Nevertheless, I was able to determine the important diagnostic fact that it permitted moderately free movement laterally, but in no other direction, a characteristic feature of nerve-tumors.

In short, every fact in the case pointed toward that diagnosis, and as the patient was almost exhausted by her sufferings she readily assented to my proposition to excise the growth. This was done under chloroform without difficulty or delay, although it is only right to record the fact that the patient came nearer to dying from the anæsthetic than any case I have ever seen during the thirty years that I have used chloroform.

Artificial respiration, energetically and persistently applied, proved ultimately successful, and she made a good recovery. In this emergency Dr. Frazer proved a cool and efficient assistant.

REMARKS.—In reference to this case Dr. Frazer recently wrote that the parts supplied by the median nerve were somewhat numb, but that there was a moderate amount of sensation and good motor power. She still occasionally complains of pain in the course of the nerve, but the severe lancinating pains are entirely gone, and the patient looks and feels better than she has done for many years. This case serves to impress the principle that nerve-tumors, if amenable to treatment at all, should be excised. It might also be used to teach the people of Michigan that there are worse things than nerve-tumors, and that of all the ills that human flesh is heir to, the cruelest and most cold-blooded is the quack.

CASE IV. *Tumor of forehead.*—E. S., aged twenty-nine years, a resident of Marshall, Mich., came to my clinic at Ann Harbor, April 8, 1889. Two months previously the patient had received a slight bruise over the middle of his forehead, which was rapidly followed by the growth of a cystic tumor. For this he consulted Dr. Smiley, who tapped the cyst, and on its refilling repeated the operation and

injected iodine. Still it did not disappear, but rather grew worse.

On admission the patient was in good health, but much alarmed about the tumor, which being about the size of a small orange, caused serious disfigurement as well as a good deal of pain.

Pulsation was a marked feature of the growth. Profiting by Dr. Smiley's experience I determined upon radical measures, and at once proposed excision, to which the patient promptly assented. Chloroform having been administered, I made a crucial incision of a sufficient extent to afford free access to the tumor, which I then dissected out from its intimate attachments to the tissues. It was necessary to execute the latter steps of the operation with great care, as the tumor had caused absorption of both tables of the skull, and was intimately attached to the dura.

Its removal was safely accomplished, and the wound carefully dressed antiseptically, and with every facility for free drainage. In three weeks the wound had healed, and the patient was dismissed cured, and, so far as I know, he has continued well.

REMARKS.—It seems very strange that so slight an injury should have resulted in the development of a thick-walled, rapidly-growing, cystic tumor, and that complete absorption of the bones of the forehead should have followed in so short a time. It is also rather remarkable that no further trouble has developed at the seat of operation. It is only reasonable to suppose that in this case a small, unobserved cystic tumor had previously existed, and that the injury caused its rapid development.

CASE V. *Complicated injury of the shoulder-joint.*—H. B. M., aged forty-two years, of Alepna, Mich., had always enjoyed good health until the receipt of the injury to be described.

On December 12, 1889, while employed at his trade of a millwright, the patient received a blow by the falling of a beam fifty feet long and ten by twelve inches thick. The blow was received on his right shoulder and arm. He was knocked first against another timber and from there precipitated to the hard, frozen ground fifteen feet below. A comrade working with him was so severely injured by the falling beam that he died soon afterward.

Investigation ultimately demonstrated that Mr. M.'s injuries consisted of:

1. Fractures of several of the upper ribs near the sternum.

2. Similar fractures near the articulation of the ribs with the spine.

3. A fracture of the anatomical neck of the scapula; that is to say, the glenoid cavity was broken off, and, with the head of the humerus, was carried downward and inward so as to rest upon the thoracic wall below the clavicle.

4. A fracture of the body of the scapula, so that the axillary margin of the bone was completely detached, and driven into the axilla, where it was afterward found lying parallel with the shaft of the humerus.

5. A fracture of both bones of the forearm.

As might reasonably be expected in so complicated a case, some of these lesions were overlooked by the medical men who first examined him.

Within a few days, however, an effort was made to restore the head of the humerus to its proper position, and this effort was repeated several times, but proved unsuccessful.

Five weeks after the injury the patient called on me at Detroit, and on examination I found that while the fractured ribs and forearm had united, the entire right arm was in a position that rendered it a useless and distressing burden. Throughout its entire extent it was greatly swollen and œdematous; voluntary power was absolutely lost, although a slight degree of passive movement could be made at the upper end where the head of the humerus rested on the ribs. The elbow, wrist, and fingers were immovable. Excessive deposits of callus had taken place at the different points of fracture. It would hardly be possible to imagine a more uninviting or unpromising case for treatment.

On careful consideration two courses seemed open in the way of operative interference, viz.:

1. Amputation at the shoulder-joint, which would give the patient—a young, strong man—a good prospect of rapid recovery, though with the loss of his right arm.

2. Something in the nature of a resection of the upper end of the bone, by which a more or less useful arm might be preserved. It was only too plain that unless something very decided could be done to relieve the mechanical obstruction in the axilla, and to improve the general condition of things in that region, amputation would be desirable, as the arm was neither useful nor ornamental to the patient. Of course, without operation, any chance of material improvement or relief was out of the question.

February 18. I operated, having previously obtained the patient's full consent. The operation was undertaken for the purpose of discovering the precise condition of things in the neighborhood of the shoulder, and with the determination to rectify these, if possible; but it was also distinctly understood that, if necessary, the arm should be amputated.

I began by making a long, straight incision down to the humerus, exposing the head and upper part of the shaft, which were deeply imbedded in inflammatory deposit. The head was lodged in and firmly articulated to a well-formed glenoid cavity, which, from its depth and capaciousness, looked more like the cotyloid cavity of the hip-joint.

Careful examination at this stage of the operation conclusively demonstrated that without removing the upper end of the humerus further progress was out of the question. Consequently this was done, with much difficulty, by means of the chain-saw. Serious obstacles to the return of the upper end of the humerus to anything like its original position still existed, and it also appeared that a large, dense mass was in the axilla, in close relation to the upper end of the shaft of the humerus. To this I naturally attributed the compression and strangulation of the extremity as a whole, and I determined to investi-

gate still further, and, if possible, to remove the mass. With extreme difficulty, and in the face of a great dread of inflicting injury upon the axillary nerve and vascular trunks, I at length succeeded in dissecting out and removing a fragment of bone. This fragment was the inferior costa of the scapula deprived of its glenoid cavity, which latter had been broken off and carried inward with the head of the humerus.

When the removal of this fragment had been safely accomplished everything assumed a much more favorable appearance. The arm was easily restored to a comparatively natural position, and the wound was dressed as after an ordinary resection of the shoulder-joint, a counter-opening having been made so that the fluids could find ready escape from the large and deep cavity left by the operation.

No important vessels were wounded, but the operation was a long one, and a considerable amount of blood was lost. Still, the patient rested well, and, although pretty extensive suppuration occurred, he made a good recovery. The most, if not the only, unsatisfactory part of his condition is the persistent stiffness and swelling of the hand and fingers, for which, in my opinion, the fracture of the radius and ulna is chiefly to blame. But even this will, I hope, in time be relieved.

In the performance of the operation here described, as well as of many others, I was ably assisted by Drs. W. G. Henry, F. W. Mann, and Abbott.

CASE VI. *Suppuration, with destruction of the entire left lung, treated by resection of ribs and drainage.*—E. B., aged eight years, was first brought to me at my clinic at Ann Arbor, in June, 1889, when I diagnosed an abscess of the lung, and recommended an operation for the evacuation of its contents and drainage, but I was not afforded an opportunity to carry this into execution. Before long, however, an opening was made by another doctor, who simply punctured the cavity through an intercostal space, and at its upper part. Great aggravation of all his symptoms followed this procedure, and some weeks later he was brought to me in Detroit. By this time the little fellow was in a deplorable condition of weakness and emaciation from excessive discharge of the most fœtid pus, and, of course, with septicæmia.

I now lost no time in making an effort to save his life, although it seemed almost too late. The cavity was tapped, and thoroughly drained by excision of a portion of two ribs, the ninth and tenth, at the lowest point of the abscess-cavity. Through this opening an enormous quantity of horribly offensive pus was evacuated; the cavity was thoroughly douched with hot water, and a large drainage-tube was inserted, through which daily ablutions with boric acid solution and other medicaments were easily and painlessly effected. The quantity of the discharge rapidly diminished, and its quality improved. In a few days the tube was dispensed with, but the ablutions were continued for several weeks. The child's health gradually improved, the discharge entirely ceased, and he is now in perfect health.

CASE VII. *Osteo-sarcoma of the scapula.*—William W., aged twenty-six years, married, a resident of Grand Haven, Michigan, was admitted to the Hospital of the University of Michigan, May 10, 1889, suffering from a large and rapidly-growing tumor of the scapula. Patient was tall, slim, and apparently very delicate. He stated that he had been in his usual health until seven weeks previously to admission. At that time he first observed the growth in his shoulder. It had given him no pain until during the past two weeks, when he received a severe wrench of the arm and shoulder, and from that time on he suffered severe pain, and the tumor grew more rapidly. It had been diagnosed as abscess, and incision recommended.

I at once suspected osteo-sarcoma limited to the scapula, and advised the operation of immediate excision of that bone. The patient's anæmic and emaciated condition, however, made me hesitate, and I placed him on tonic treatment and determined to wait for some improvement in his health. This took place, so that on May 28th, I performed excision of the entire scapula. Chloroform having been administered, I made an incision from the point of the acromion process backward, along the superior margin of the scapula, to the median line of the back, and from the middle of that incision a vertical one downward, to a point at least two inches below the lower angle of the bone. With these free external incisions I was sure to have plenty of room for the subsequent steps of the operation. The hæmorrhage from these preliminary incisions was very severe, and it seemed that the only chance of safety consisted in a rapid completion of the operation. I first freed the posterior margin and the lower angle by rapid sweeps of the knife. I then disarticulated the shoulder-joint, and finally separated the deep attachments of the bone in front and above. The suprascapular artery, much enlarged, was divided and instantly secured. The subscapular was also much enlarged, and was divided and ligated half an inch from its origin from the main trunk. Numerous smaller branches were also ligated. Although the patient was in the amphitheatre only twelve minutes in all, and although every precaution was taken to limit the flow of blood, still a good deal was lost, and he suffered very seriously from the shock, for which stimulants were freely administered. In about twelve hours reaction was fully established.

The subsequent progress of the case was extremely satisfactory. One week from the date of operation the patient walked into the amphitheatre to have his wound dressed, when it was demonstrated that the whole extent of that vast wound had healed by first intention. In three weeks he was dismissed in good condition, and with every prospect of complete restoration to health. Before leaving the hospital he had recovered good movement of and control over the arm.[1]

The tumor was examined by Dr. Gibbes, who pronounced it osteo-sarcoma. The specimen is now in the University Museum.

REMARKS.—Before leaving this case I desire to refer very briefly to the history of the operation of exci-

[1] Since the above was written I have heard with regret of the death of this patient from causes unconnected with the operation.

sion of the entire scapula, and to recall some practical deductions in relation to it. Professor Syme performed this operation in 1856, with at least temporary success, and he believed that no one had preceded him. In a brief preface to his paper, entitled, "Excision of the Entire Scapula," he says: "In the present advanced state of surgery any real addition to its resources must be regarded as a subject of interest. I, therefore, venture to hope that the following account of an entirely new operation will be deemed worthy of separate publication."

Syme's first case was performed in the Royal Infirmary of Edinburgh, October 1, 1856. He was, however, mistaken in believing that no one had preceded him, for Langenbeck had done it successfully a few months previously. This fact, however, does not in the least detract from the merits of Syme's work, which was certainly original and independent. Not only so, but he has left behind him a description of the *modus operandi*, as well as a summary of the principles involved, which, bearing as it does the unmistakable stamp of his surgical genius, will stand for all time as the most authoritative utterance on the subject.

From his first case he deduced the following doctrines:

1. "That the entire scapula may be disarticulated from the shoulder-joint without loss of blood to any great extent.

2. "That the wound resulting from this operation does not necessarily occasion an excessive amount of discharge.

3. "That the arm which remains is not a useless appendage, but a serviceable limb."

So far as I have been able to learn, the tumor removed in my case is by far the largest on record, as it weighed about eight pounds.

In my operation every effort to secure asepsis was used, and certainly the union by the first intention of so extensive a wound might justly be quoted as a testimonial to our modern methods, of which my celebrated preceptor, in 1856, had never even dreamed. But let me quote his own words, immediately following the description of his operation:

"Everything went on favorably after the operation, and a great part of the wound healed by the first intention."

According to the *International Encyclopædia of Surgery*, forty-two cases of excision of the entire scapula have been recorded. Of that number, eight were by American surgeons, and of the whole number exactly 20 per cent. died.

72 Lafayette Avenue.

The Death of Dr. Frederich Arnold.—The death is announced of Dr. Frederich Arnold, emeritus professor of anatomy in the University of Heidelberg. Dr. Arnold was nearly ninety years of age.

COCOANUT-WATER AS A CULTURE-FLUID.

By GEORGE M. STERNBERG, M.D.,
Major and Surgeon, U. S. Army.

The fluid contained in unripe cocoanuts is known in the West Indies as *agua coco*, or cocoanut-water. Unlike the fluid contained in the ripe nut, which has a milky appearance, it is perfectly transparent.

In countries where the cocoanut is indigenous this *agua coco* is very popular as a refreshing drink, and by some is thought to possess valuable diuretic properties. At railway stations in the country, and at places of refreshment in towns, piles of the unripe nuts are to be seen, and at a moment's notice one may obtain a tumblerful of the fluid at very small expense.

At the time of my first visit to Cuba, in 1879, the idea occurred to me that this fluid might be a useful culture-medium for bacteria, and upon making the experiment I found that various species grew in it most luxuriantly.

As it is contained in a germ-proof receptacle no sterilization of the fluid is required when it is transferred with proper precautions to sterilized test-tubes, or is drawn directly from the nut into the little flask with a long and slender neck, which I am in the habit of using for fluid cultures. In these it may be preserved indefinitely, remaining perfectly transparent and ready for use. Heating the fluid causes a slight precipitate.

In the investigations which I have made in Havana during the past two years I used this fluid very extensively and found it a great convenience to have a sterile culture-fluid always at hand ready for use at a moment's notice. Moreover, it has certain special advantages for the study of the physiological characters of various bacteria and for the differentiation of species. It contains in solution about four per cent. of glucose in addition to vegetable albumin and salts, which alone would make it a useful nutrient medium.

Certain microörganisms multiply in it without appropriating the glucose, while others split this up, producing an abundant evolution of carbonic acid, and giving to the fluid a very acid reaction. As obtained from the nut it has a slightly acid reaction, which makes it unsuitable as a culture-medium for certain pathogenic bacteria, but when desired it is a simple matter to neutralize it. For a large number of species of bacteria and for the saccharomycetes it constitutes a very favorable medium. Since my return from Cuba I have obtained an analysis of this fluid through the kindness of Professor Remsen, of Johns Hopkins University. Six unripe cocoanuts sent to me by my friend, Dr. Daniel Burgess, of Havana, were placed by Professor Remsen in the hands of Mr. L. L. Van Slyke,

Ph. D., for chemical examination. I have received from Dr. Van Slyke the following report of the results of his analyses:

1. Weight of fluid obtained from each nut varies from 230.5 grammes to 383.7 grammes, the average being 339.1 grammes.

2. The specific gravity (at 15.5° C.) varies from 1.0215 to 1.0246, the average being 1.02285.

3. The amount of water in the fluid from each nut varies from 94.37 per cent. to 96.43 per cent., the average being 95 per cent.

4. The amount of ash or inorganic matter in each varies from 0.575 per cent. to 0.675 per cent., the average being 0.618 per cent.

5. The sugar is mainly in the form of glucose, with traces of cane-sugar. The amount of glucose varies from 3.45 per cent. to 4.58 per cent., the average being 3.97 per cent.

6. The fat varies from 0.084 per cent. to 0.145 per cent., the average being 0.119 per cent.

7. The amount of albuminoids in each varies from 0.095 per cent. to 0.205 per cent., the average being 0.133 per cent.

HYSTERICAL APHONIA.

With Especial Reference to a Plan of Treatment, and with the Report of Cases.[1]

BY J. A. BACH, M.D.,
OF MILWAUKEE, WIS.

ONE of the many manifestations of hysteria is the so-called hysterical paralysis of the muscles of the vocal cords, resulting in aphonia, a condition that is most interesting and instructive, inasmuch as it can be so readily observed from its full development to perfect cure. The lack of proper central stimulation is well illustrated here. Examination with the laryngeal mirror shows the cords to be of nearly a normal color. If a strong effort at intonation be made by the patient, the cords quickly approximate but as quickly recede, so that voice is not produced, although apparently the effort of the patient is continued. The central nerve-stimulus is lost and the muscles of phonation are practically paralyzed. This condition is often accompanied with paresis of the muscles of the tongue and pharynx.

It is well established that the impediment to conduction is not situated in the peripheral motor nerves, for the electrical reaction remains normal. It would further seem, from the results of treatment in the following cases, that there is no impediment at all to conduction, but only a lack of the production and correct application of a central stimulus.

The etiology of hysterical aphonia is similar to that of other hysterical conditions. It is less a local trouble than a general one manifesting itself locally. In many cases no cause is apparent, and the voice may disappear either suddenly or gradually. The affection is limited to the period between puberty and the menopause.

Treatment.—The various modes of treatment practised and advocated have met with success in probably the majority of cases, but the results have often been only temporary or incomplete. This has been the result with the various methods of electrical treatment, whether centrally or locally directed: also, with the administration of the different nerve tonics and sedatives, as well as with other medicinal means. Furthermore, the time consumed in securing definite results has, in many cases, been considerable.

The plan of treatment to which I wish to draw special attention proposes to do away with all such means, and teaches the patient inductively to regain control of the larynx, to innervate properly the muscles of the cords, and to produce voice as a beginner on the cornet would learn to produce his first tones.

The greatest difficulty with the hysterical patient is the production of the first tone, as such patients are generally unable, through their own efforts, to produce any sound whatsoever. This initial difficulty, however, can always be overcome in a few moments by the assistance of reflex action. For this purpose a strong irritant, whether mechanical or chemical, may be applied to the larynx so as to excite cough. This, of course, requires no effort on the part of the patient. Having excited this cough once or twice the patient will be able to reproduce it independent of the irritant. The cough is short and of an explosive character.

After repeating the cough five or six times the patient will have gained sufficient control of central stimulation to produce a cough. It now becomes a simple matter to continue this cough and to pronounce, more or less distinctly, the vowel "*a*" at each effort, and after a few efforts to substitute the vowel "*e*," and so on, until all the vowels have been coughed. After this is repeated several times, the element of cough can easily be eliminated from the vocalization, when we have left the pure vowel-sound, which, without effort on the part of the patient, can be combined with consonants, as, for instance, with "*d*"—"*ad*," "*ed*," "*id*," "*od*," "*ud*," first placing the vowel before the consonant and then reversing this. It would not be advisable to attempt the articulation of words at this stage, but better to combine the vowels with single consonants, gradually increasing the duration of the sound. The patient is thus led to speak words without resisting, wilfully or unmiten-

[1] Read before the Milwaukee Clinical Society, June 10, 1890.

tionally. The time occupied in this procedure need not be more than half an hour, although it is advisable to give several treatments, in order to place the patient beyond the possibility of relapse by impressing her with the fact that she produced the sound by her own efforts, and that it is due to a lack of effort if the voice is again lost. Show her how, by coughing if necessary, she can go through the same process as before.

A report of the following cases will illustrate results obtained in apparently unfavorable subjects.

Case I.—Miss B., aged twenty-eight years, poorly nourished, anæmic, and of a neurotic type, came under my care for treatment in June, 1889. For about seven years she had been unable to speak or whisper, and she carried with her a tablet upon which all communications were written. She was very despondent, and had but little hope of relief, as she had had nearly continuous treatment of various kinds for more than three years.

Upon examining the larynx I found a very characteristic picture of hysterical paralysis of the vocal cords, and, in addition, an infiltration of the ventricular bands, yet not sufficient to prevent the proper action of the cords. Although the paralysis had existed so long the resulting atrophy was not very marked. One peculiarity of the case was her imagined inability to whisper. As her breathing power was fair there was no good reason for this complication. The patient was of a fairly intelligent class and I explained to her the condition as well as I could, assuring her that with her coöperation it would be perfectly possible to effect a cure in a short time. After having shown her the folly of not being able to whisper, and that whispering is not a function of the vocal cords or larynx, and is produced by the modifying influences upon the breath by organs above the larynx, she gained confidence, and I had at least a whisper to begin with. It now remained again to direct properly central innervation of the vocal muscles, which, according to the plan proposed, was accomplished as readily and in as short a time as if she had been aphonic for only a week. The other pathological conditions of the larynx were treated for some time before the patient was discharged.

Case II.—Mrs. J. H., a Jewess, aged forty-three years, married. This lady was well nourished and in perfect general health, but for about ten weeks had been unable to speak, for which difficulty she had been treated without result. The laryngeal picture was one of hysterical aphonia, with considerable congestion; no other changes were found. Patient asserted that she had contracted the trouble through a severe cold, but I elicited the additional fact that a quarrel in the family about the time of contracting the cold played a rather more important factor than the cold itself.

Treatment was applied as in the preceding case, and at the second visit the patient was discharged, perfectly cured.

Case III.—Miss W. B., a teacher, aged thirty years; well nourished, and of a neurotic type, had, seven months previously, lost her voice. In consequence of this she was obliged to give up her occupation as teacher.

During this time she had been under various modes of treatment by different physicians. One doctor told her that her throat and larynx were "swollen shut."

Here again the laryngeal image was characteristic. The condition was uncomplicated, and my prognosis was favorable. The treatment resulted in a cure in fifteen minutes, although she made a second visit before I discharged her.

The results in these cases were so satisfactory and so direct that all other means of treatment would seem superfluous.

It has occurred to me that, could other hysterical conditions be brought under such direct control and treated upon a similar plan, we would not so frequently hear of Christian science and faith-cures after so-called medical science has failed.

CLINICAL MEMORANDA.

SURGICAL.

A Case of Malignant Disease of the Kidney.—February 14, 1890, I was called to see J. J. P., male, aged forty-three years, a farmer by occupation. His pulse was 100, and his temperature 99.2°. He complained chiefly of a lame back and pain in the lumbar region, extending down the thighs to the knees, and occasionally to the ankles, on attempting to move. The pain was more marked on the left side than on the right. He was able to move about on crutches, and was more comfortable while sitting up than when lying down. Just before my visit he had had several paroxysms of severe pain in the region of the stomach, accompanied with dyspnœa.

Upon examination I found a tumor in the left lumbar region, extending from the last rib to the crest of the ilium and the same distance transversely, with its centre about at the external border of the erector spinæ muscle. With a hypodermic syringe I drew out, from about one inch below the surface, a sero-sanguinolent fluid, which was odorless. Upon inquiry I found that his previous health had been good, as was also his family history.

His account of his present illness was as follows: About June 1, 1889, he began to be troubled with pain and lameness which interfered with his work. He also could feel what he described as the sensation of a lump in his abdomen. As time passed on, the original sensation of a tumor was replaced by pain. He was seen on November 23d, and again December 23d, by a reputable practitioner, who treated him for rheumatism. From December 23d, he was confined to his home.

In January he was seen by another practitioner and the first diagnosis was confirmed, although the tumor was at that time quite prominent. As the other symptoms increased the patient began to be troubled with constipation, which was evidently due to pressure on the descending colon. At no time was there much pain in the tumor itself.

I did not examine the urine microscopically, but chemically I could detect nothing abnormal except an excess of urates.

I could get no history of anything that threw light on the case, except a sprain of the back, in April, 1889.

My diagnosis was nephritic or perinephritic abscess, and I advised an operation.

February 21st, Dr. G. L. Pritchett, of Fairbury, Neb., saw the patient with me, confirmed my diagnosis and also advised operation. He thereupon proceeded, with my assistance, to open the cavity by a free incision about midway between the last rib and the crest of the ilium, extending in the direction of the fibres of the external oblique muscle. About a pint of sero-sanguinolent fluid and broken-down tissue, apparently kidney tissue, escaped. All parts within reach of the finger seemed to be normal except the kidney, which was so disorganized to be unrecognizable. The wound was irrigated with bichloride solution, a drainage-tube inserted to a depth of three inches, the cavity packed with iodoform-gauze, and dressed externally with iodoform-gauze and bichloride cotton.

There was considerable discharge at first; later it grew less but never stopped.

The results of the operation were the disappearance of pain and great relief to the patient. On March 15th he walked from his chair to his bed without crutches for the first time for two months. His temperature had gradually fallen to normal. He sat up from one to four hours a day after March 10th. Until March 15th he improved so much that his ultimate recovery seemed certain. On March 7th I dressed the wound with bichloride-gauze and stopped using iodoform, after which there was more pus. Between March 29th and April 14th, I opened three small cavities, containing pus, near the original opening; one in the cicatrix formed by the partial healing of the first operation. In each I inserted a tube to a depth of from two to four inches.

On April 20th, Dr. G. L. Pritchett, assisted by Dr. Eaton, of Fairbury, Neb., and myself, again opened the cavity, removed much broken-down tissue and packed the wound with bichloride-gauze. The patient's general health did not fail much until June, but the wound was more unhealthy after about March 15th. It did not heal after the second operation, but grew deeper and small cavities occasionally opened into the main one. The swelling increased until it was about ten inches in diameter. It also seemed to increase internally and to press on the nerves—causing a return of the original pain though to a less severe degree.

From April 1st, the temperature varied irregularly from the normal up to 104°, and there was an occasional chill. After the first operation he had attacks of vomiting, but during most of the time his appetite was good. About June 15th, he became unable to sit up, and the discharge increased and was very fœtid. From then until his death, June 26th, the discharge was so great that it was necessary to place an oilcloth under the sheet, and to change the bedclothes several times a day. The odor became very offensive. Gangrene appeared about two days before his death, that is, in the parts exposed to view. Judging from the odor I am sure that internally it commenced earlier.

For about a week before death the urine was much diminished in quantity. It contained no albumin. Further examination was omitted for want of instruments.

Death occurred by asthenia. My opinion is that the abscess was caused by a malignant growth, although no autopsy was held.

A. C. AMES, M.D.

REYNOLDS, NEBRASKA.

Abscess of the Prostate Cured by Perineal Section.—Abscess of the prostate of idiopathic origin is sufficiently rare and serious to warrant the report of the following case:

Mr. C., aged seventy-two years, a prominent agriculturist and legislator, was attacked quite suddenly with pain in the perineum and anus. He had suffered for several months from constipation, and thought the "straining at stool brought on piles," as he expressed it. His family physician gave him some soothing ointment, but it afforded him no relief. The parts about the anus became greatly swollen, evacuation of the bowels was very painful and the urine was voided with great difficulty. He had fever, lost appetite, and had remitting pain of a throbbing character.

I saw him in consultation after he had been sick a week. He was delirious, had chills every few hours and profuse sweats. Anodynes and quinine were being used freely. The parts about the anus were so œdematous that a digital examination *per rectum* could be made only with difficulty. However, a smooth oval tumor was felt in the region of the prostate. It encroached upon the rectum and appeared to push the bladder upward and backward, elongating the urethra. There was no history of previous urethral or vesical disease, and a sound met little obstruction on the way to the bladder.

I diagnosed an abscess and felt an indistinct sense of fluctuation on placing my finger in the rectum behind the tumor and pushing it forward toward the perineum, where I made counter-pressure with the finger of my other hand. Without an anæsthetic a sound was passed into the bladder and given to an assistant to hold, as in the operation for perineal lithotomy—the patient being in the lithotomy position. Then I pushed or pulled the tumor down against the perineum with a finger of my left hand in the rectum, and introduced the point of a straight bistoury through the integument in the median line of the perineum about one inch in front of the anus, and pushed the blade straight back into the tumor, while the urethra was held up out of the way of incision by my assistant with the sound. As the pus began to flow the incision was carried toward the anus until it was free enough to empty the abscess thoroughly, which contained about two ounces of pus.

The subsequent treatment was washing the abscess cavity daily with a fifty-per-cent. solution of peroxide of hydrogen and the internal use of bitter tonics. The patient's recovery was perfect and uninterrupted.

HAL C. WYMAN, M.S., M.D.,
Professor of Surgery in the Michigan College of Medicine and Surgery, Detroit.

OBSTETRICAL.

Double Cephalhæmatoma.—A cephalhæmatoma on either parietal bone in a newly-born infant is quite common.

There is probably not a general practitioner of any experience in obstetrics who has not become familiar with it. At least ten have been seen by the writer in hospital and private practice. A double hæmatoma, on the contrary, is very rare and gives the infant's head a much more deformed appearance. Curiously enough, two cases have occurred in the writer's service in the Maternity Hospital within eighteen months. The first was bilateral, on each parietal bone, and unusually large; it was reported in the *University Medical Magazine*, with an illustration. The second has been under observation for more than three months. The blood-tumors were situated on the right parietal bone and on the right side of the occipital bone. Each was as large as though a small crab-apple had been inserted under the scalp, and the two together gave the head a very curious appearance. They appeared three days after birth. The mother was a primipara, and the labor lasted in its three stages respectively six hours, two hours, and ten minutes. The labor was easy, the position of the vertex was right occipito-anterior. Nothing was done for the tumors and they slowly subsided; but still, three months from their appearance, there are decided lumps on the infant's head. If the blood-tumor is large, and if the child cannot be kept under observation a long time, it is a question whether it would not be better to aspirate antiseptically about a week or ten days after the formation of the tumor, as at this time there would be little likelihood of a fresh subcranial effusion.

Barton Cooke Hirst, M.D.,
Professor of Obstetrics in the University of Pennsylvania.

MEDICAL PROGRESS.

The Uselessness of Quinine in Non-malarial Diseases.—We use the term "malarial" to define a certain group of symptoms, but more frequently to hide our ignorance of the true nature of diseases, especially of those that are attended with febrile phenomena. Hence the common use of quinine in many varieties of diseases.

The observations of Roux, Laveran, Collin, and others, have almost established the fact that malaria is a disease of the country, and that large cities seem gradually to create for themselves an immunity against paludal disorders.

Dr. Joaquin L. Dueñas (*Crónica Médico-Quirúrgica de la Habana*, Havana, July, 1890, No. 7) publishes an able article on the use of quinine in a variety of diseases, and his results corroborate the experience of Laveran, Maillot, Dutrenlean, Jaccoud, and others, with regard to the use of the drug in the treatment of disease.

Dr. Dueñas's observations were made in Havana. He asserts that this city, contrary to what might be expected, is particularly free from malarial infection, and that it is only in a few sections of the town, where the pavement is imperfect, and where there is much decomposing organic matter, that cases of true malarial fever are met. Thus, of 3961 patients treated by him in the course of nine consecutive years the death-rate was only $7\frac{1}{16}$ per cent. Of this large number of persons, 1694 suffered from apyretic disorders, while 2267 presented febrile symptoms. Of these fever cases, 774 were of an infectious character, and of the latter only 70 could be classed as malarial, thus: intermittent fever 42; remittent fever 18; pernicious fever 6; malarial cachexia 4. Of the 8 deaths from paludal poisoning, among the 70 cases, 6 were due to pernicious fever and 2 to remittent fever. The remaining 704 pyretic affections comprised typhoid fever, yellow fever, smallpox, varicella, measles, scarlatina, miliary tuberculosis, erysipelas, and septicæmia.

With regard to the employment of quinine in this large number of cases, Dr. Dueñas used it extensively in the 70 malarial cases, and in the non-malarial diseases, only in a certain number of cases of typhoid fever and erysipelas.

In the 1694 cases of a non-febrile character the remedy was employed more especially as a cardiac and vascular tonic and as a nerve stimulant. Of these cases, 1435 completely recovered, 83 died, and the results in 173 could not be ascertained, giving a mortality of 5.65 per cent. The diseases most commonly met with were the catarrhal affections of a rheumatic origin, neuroses, chlorotic neuralgias, and scrofula.

Quinine was found of great service in certain congestive conditions, in hæmorrhages, non-febrile rheumatism, idiopathic and constitutional neuralgias, migraine, asthma, cardiac weakness, whooping-cough, and in other diseases, which, although not dependent upon malaria, frequently assume the intermittent type. Of all these latter diseases, neuralgia was found to be the most frequent, and it yielded easily to the use of quinine. Of 228 cases treated successfully by the drug only two were due to a distinct malarial poisoning.

But the most important part of Dr. Dueñas's experience is with reference to the employment of the drug in febrile disorders not dependent upon malaria. Of the 2267 cases of this nature treated, 993 were catarrhal affections and diseases of the mucous membranes; 774 infectious pyrexias; 272 organic and other inflammations; 124 tubercular and rheumatic diseases, and the remainder were such specific diseases as diphtheria, dysentery and tetanus, and ephemeral or continued fevers.

Although possessing excellent antiphlogistic and antiperiodic properties, quinine was often harmful in certain catarrhal affections of the respiratory apparatus, such as laryngitis, bronchitis, and acute broncho-pneumonia. In these diseases a marked reduction of temperature after the administration of quinine was never observed.

The same results were observed in the treatment of catarrhal affections of the digestive organs. In cases of mucous and hepatic disease, in febrile stomatitis, and in acute gastritis, the temperature could be lowered only by means of ipecacuanha, and the resolution of the disease was hastened by the application of local emollients, rest, diet, and hygienic measures. It was noticed that in such cases quinine prolonged the febrile stage and the duration of the disease. Cases of acute enteritis, enterocolitis, cystitis, endometritis, and other local diseases of the mucous membranes, were successfully treated without the aid of quinine. In many of the cases the drug exercised an injurious influence, even when the disease was malarial. The drug was also found harmful, and even hastened death, in cases of infantile broncho-pneumonia.

In the infectious febrile disorders, Dr. Dueñas used the remedy only to reduce high fever and as a cardiac and vascular tonic, except in cases with malarial symptoms. He employed it in moderate amounts in some septicæmic diseases, in erysipelas, in typhoid fever, and in miliary tuberculosis; but never in smallpox, measles, scarlatina, or yellow fever. After a short experience the drug was discontinued in the treatment of typhoid fever and septicæmias.

It was found useless in malarial disorders of an adynamic type. In the few cases of pernicious fever in which quinine was used as the chief remedy, death was invariably the result. But whether death was due to the medicine or to the disease cannot be determined.

In malarial remittent fever, quinine produced excellent results; but in those forms of disease known as typho-malarial, in which the most prominent symptoms are typhoid, the uselessness of quinine was most remarkable. Here the drug, owing to its local action, prolonged the irritation of the gastro-intestinal mucous membrane: besides, it seemed to weaken the system, to diminish organic resistance, and to predispose the patients to attacks of syncope, in which the degeneration of the cardiac fibre was a frequent cause of death.

The remedy was found useful in erysipelas and in the treatment of acute articular rheumatism, but useless in dysentery, diphtheria, and all forms of septicæmia, especially that occurring in the puerperal state.

In localized cerebral congestions dependent upon tubercular disease, quinine often did good when given in moderate doses. In the hyperæmia of the meninges, so frequent during the period of dentition, and in other infantile disorders, the alkaloid produced most brilliant results in doses of from 3 to 4 grains, according to the age of the patient. On the contrary, in meningeal irritation due to anæmia, the remedy was not only useless, but dangerous.

Dr. Dueñas found quinine useless in the fever of syphilitic, chlorotic, and hysterical subjects, and in the fever of dentition.

Treatment of Pediculi Pubis.—

℞.—Vinegar . . . . 5000 parts.
Corrosive sublimate . . 1 part.—M.

This is said to be recommended by Brocq.—*Revue Thérapeutique Médico-Chirurgicale.*

Treatment of Paroxysmal Tachycardia.—Huchard, in a clinical lecture delivered at the Hospital Bichat, gives the following directions as to the treatment of this severe affection; dividing the treatment into first that devoted to the care of the patient during the attack, and second, to his care between the paroxysms.

If the man is standing, he must be made to lie down on the right side in as nearly a horizontal position as possible, and every measure taken to relieve him of mental or physical disturbance. Compression may be applied over the right carotid artery, while in some cases a deep inspiration may give relief. In either case the remedial result is due to the effect on the vagus nerve. While these measures are useful in some cases, Huchard himself employs others, such as the application of a bichloride of methyl spray to the præcordium, the back of the neck, or the chest. Sometimes active vesication over the præcordium is useful. He also gives at the time of the onset of the attack, digitalis by the mouth, if possible, or, if the stomach is irritable, by rectal injection, and finds that in moderate doses it does great good. When the attack is prolonged and threatens life, and when cardiac dilatation is imminent, venesection may be resorted to, or, in a plethoric person, local bloodletting from the præcordium be carried out. When cardiac weakness is very marked and syncope is a pressing symptom, hypodermic injections of ether or caffeine may be used, and nitroglycerin given or nitrite of amyl inhaled. These last remedies are absolutely contraindicated in those instances in which low arterial tension already exists.

The stage of intermission is to be treated by dieting and the proper use of drugs. The patient must take neither coffee, tea, nor alcoholic drink, nor must he use tobacco. All stimulating foods must be forbidden, and everything done which will tend to efface any tendencies to subsequent attacks. In each case we must seek for a cause and overcome it. Huchard uses arsenic as a general systemic tonic, and as an alterative particularly affecting the nervous centres. In those instances in which the arterial tension is below normal, he recommends pills of sulphate of quinine and ergot, as follows:

℞.—Sulphate of quinine } of each 1 drachm.
Aqueous extract of ergot }
Extract of nux vomica . . . 1½ grains.

Make into 40 pills, and give 2 or 3 pills two or three times a day for six weeks or two months, and accompany them with 1 to 2 drops of Fowler's solution. Digitalis may be given in constant but small doses for a long period if cardiac weakness is present. In some cases prolonged avoidance of mental or physical exertion is absolutely necessary if a cure is to be arrived at.

Treatment of Chilblain.—Boelz, of Tokio, states that the treatment of chilblain should consist, first in washing with hot water, and second in applying to the surface the following mixture:

℞.—Caustic potash . . . ¾ grain.
Glycerin } of each . 6 drachms.
Rectified spirit }
Distilled water . . . 2 ounces.—M.

This preparation is generally not too irritating, and produces a cure in the space of two to three days.—*Rev. Gén. de Clin. et de Thérapeutique.*

Syrup for Infantile Constipation.—

℞.—Podophyllin . . . 1 grain.
Alcohol . . . . 1¼ drachm.
Syrup of red raspberry . 3 ounces.—M.

Dose: from a teaspoonful to a dessertspoonful every morning, according to the obstinacy of the constipation. —*L'Union Médicale*, August 5, 1890.

Treatment of Sycosis.—Rosenthal applies the following in this condition:

℞.—Tannic acid . . . 15 grains.
Milk of sulphur . . . 30 "
Vaseline . . . . 5 ounces.—M.

During the day no applications are used, but at night the ointment is thoroughly applied. The following, recommended by Hebra, may also be resorted to:

R.—Tannic acid . . . 75 grains.
Milk of sulphur . . . 150 "
Oxide of zinc } of each . 9 drachms.
Starch }
Vaseline . . . . 1½ ounces.—M.

After the ointment is applied, it is covered with iodoform-gauze.—*Rev. Gén. de Clin. et de Thérapeutique.*

Ointment for Syphilitic Alopecia.—According to *L'Union Médicale*, July 31, 1890, MAURIAC recommends the following application for the relief of syphilitic alopecia:

R.—Sulphate of quinine } of each 7½ grains.
Turpeth mineral }
Suet . . . . . 1 ounce.—M.

Make this into a pomade, and apply night and morning. Every second day use the following wash:

R.—Carbonate of sodium } of each 15 grains.
Boric acid }
Distilled water . . . 8 ounces.

If the disease persists, a lotion of mercuric chloride of the strength of 1 to 500 or 1 to 1000 may be used, or in other instances yellow precipitate ointment will be more efficacious.

A Simple Ointment for Pruritus.—BALFOUR reports that he has almost never failed to obtain prompt relief, in cases of pruritus of the anus and vulva, from an ointment containing eighty grains of calomel to the ounce of vaseline or other unguent.

A Death from Chloroform.—M. SOTTAS (*Arch. Génér. de Méd.*, July, 1890) reports a case of death under chloroform in a patient who had previously been chloroformed on several occasions, the last time but one month prior to the fatal anæsthetization. The chloroform used was mixed with one-fourth of ethylic alcohol. The patient had been operated upon several times for tubercular disease of the bones, but was coughing very little and presented no signs of advanced pulmonary tuberculosis.

He bore the early administration well; the conjunctival reflex, the pulse, and breathing being carefully watched. The patient was turned upon his side, in order to reach the dorsal region, where a cold abscess was situated, the opening of which was the object of the operation. At this moment a general muscular contraction of the trunk took place, and he suddenly and without warning ceased to breathe. The eyelids opened, the pupils dilated, the conjunctival reflex disappeared, the face and chest became dark-colored, and, in spite of prolonged artificial respiration, electrical stimulation, oxygen inhalations, and ether injections, he gave no sign of life except a few attempts at spontaneous respiration. Two huge pockets containing pus were found at the autopsy, the one in front of the dorsal spine pushing the heart forward and displacing the aorta to the left, the other posterior to the spinal column in the lumbar region, and reaching down to the sacrum. A fistulous communication existed between the two pockets. The heart was normal in size, and filled with dark blood. The lungs were adherent to the pleura, much congested, and the aorta was slightly atheromatous.

The Effects of Salol on the Kidneys.—HESSELBACH (*Practitioner*, August, 1890) has made a valuable study of the effects of carbolic acid and salol on the kidneys. He finds that carbolic acid continuously administered to rabbits produces anæmia and fatty degeneration of the renal cortex, with disintegration and destruction of the epithelium. Salicylic acid given in the same manner produces hyperæmia of the cortex with extravasations into the interstitial tissue and the tubules. Salol given continuously produced pathological changes almost identical with those caused by carbolic acid, showing that the latter constituent and not the salicylic acid gives to salol its toxic properties.

Hesselbach deduces the following practical conclusions from his observations:

1. The large proportion of carbolic acid contained in salol renders it so toxic a substance that its unrestricted therapeutic use is fraught with danger.

2. In renal disease, acute or chronic, salol is contraindicated.

Cystitis in Diabetes.—SCHMITZ (*Berliner klinische Wochenschrift*, No. 23, 1890) draws attention to the occasional occurrence of cystitis in the course of diabetes. It is caused, he thinks, by fermentation of the saccharine urine. Schmitz distinguishes three stages of the chronic form—acute cystitis in diabetes being unusual. The first is mild with no subjective symptoms; the urine is somewhat turbid, faintly acid, and contains numerous mucous corpuscles and a few pus-cells. From this the second develops, when the urine becomes more turbid, has an unpleasant smell, and contains bacteria, phosphates, and more pus. In the third stage the fermentation may cause the evolution of gas which is passed through the urethra, and the subjective symptoms of cystitis are marked.

To cure this condition the bladder should be frequently washed out with a solution of salicylate of sodium, to prevent decomposition of the urine; the diabetes, of course, being carefully treated by the usual methods.—*Practitioner*, August, 1890.

Lactic Acid in the Treatment of Diarrhœa.—HAYEM (*L'Médecine Moderne*, July 5, 1890) calls attention to the value of lactic acid in the treatment of the diarrhœas of adults as well as in those of children. He thinks that in small doses it increases the power of gastric digestion; that in moderate quantities it is probably absorbed and changed in the blood; but that after large doses—more than 2½ drachms daily—it appears in the urine and fæces. The large doses, however, do not cause any disagreeable symptoms, and Hayem has given as much as 2½ drachms daily for several weeks. He prescribes the acid as follows:

R.—Lactic acid . . . 2½ to 3 drachms.
Syrup . . . . 6 ounces.
Water . . . . 7 ounces.—M.

Half a tumblerful to be taken between each meal.—*London Medical Recorder*, August, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 13, 1890.

GASTRIC NEUROSES.

WITHIN recent years considerable progress has been made toward a clearer understanding of the various morbid conditions which have long been classified under the rather vague and ill-defined heading of "dyspepsia," with, perhaps, the occasional addition of an adjective, like "functional" or "nervous," which added but little to our knowledge. The readers of THE MEDICAL NEWS have been kept fully informed of current researches, not only by comments in the editorial columns, but by original communications—notably a paper read by DR. FREDERICK P. HENRY before the Philadelphia County Medical Society—and by abstracts of the more important communications to other journals, American and foreign.

The highly elaborate classifications proposed by many authors might, however, be much simplified without loss to our comprehension of the subject-matter—the more so as the association of morbid states is usually complex, derangement of secretory function being usually an accompaniment of disturbance of motor function, and *vice versa*; and, as just exemplified, no matter how elaborate our subdivision of morbid conditions, we are still unable to escape from the use of such general terms as "disturbance," "derangement," etc.

To a purely palliative treatment it may, of course, make considerable difference whether the gastric juice contains an excess of acid to be neutralized by the administration of alkali or whether it is deficient in acidity, requiring artificial aid for digestion by acids medicinally ingested. And so with the other refinements as to excess or lack of secretion. The careful physician will seek to inform himself as accurately as possible of the existing conditions in each individual case. When, however, more radical treatment is considered, the question is not as to what particular aberration of secretion or motion may be present, but whether that aberration has a local or a central cause. For not only may either a local or central cause apparently give rise to similar conditions, but the same cause, whether local or central, may give rise in different individuals to dissimilar conditions.

The circumstances modifying the causative action, so that what brings about supersecretion in one case, in another brings about superacidity, and in a third, perhaps, a diminution of secretion or qualitative lack of acid, are probably transient and unimportant. They are like the currents of wind determining the fall of an apple upon this or that particular spot; while the determining cause of aberration, independent of its direction, is some imperative action, like the gravitation which makes the apple fall, whether here or there.

REMOND (*Archives Générales de Médecine*, June, 1890) publishes a contribution to the study of "Mixed Neuroses of the Stomach," which contains the history of several instructive cases. In one the predominant phenomenon was excessive secretion, which occurred with any excitation or even independent of excitation. In such a case we have, evidently, an instability of the nervous apparatus controlling secretion, an excessive catabolic action, leading, eventually, to a failure of compensatory anabolic action, when the phenomena presented would be those of deficient secretion—a want of catabolic action for lack of material. But an original nervous disturbance might have taken the reverse direction, so that what appears in the case referred to as a secondary condition is, no doubt, in many cases primary. Thus, Remond, in the article cited, collates a considerable number of cases of disturbance in the secretory function of the stomach presenting very diverse phenomena, occurring principally in hysterical patients and in ataxics. Finally, he traces by the following path the connection between supersecretion and that

condition of atony to which Meyer has given the name *phthisis ventriculi*.

The stomach, from some morbid state of its nervous apparatus, secretes an abnormal gastric juice. The patient has pyrosis; the stomach at each meal responds with undue activity to the stimulation of food, and finally vomiting occurs to relieve the viscus from the excess of acid. The vomiting, on the one hand, increases the irritability of the nervous apparatus of the stomach, and, on the other, depresses the patient's spirits, thus adding to the original trouble. The morbid activity of the glands is increased until, finally, exhaustion occurs, and they fail to respond to any stimulus, dilatation and wasting being the final results. Remond does not agree with Rossbach, Riegel, and others, who attribute dilatation to spasm of the pylorus from irritation by too acid a secretion. The long duration of his first case, without dilatation, negatives this, to his mind. He believes that histological alterations are produced in the secretory structures—a sclerosis, in fact, which may either seal up the orifices of the glands, producing retention-cysts, if of superficial origin; or destroy their secretory cells, if of deeper location. As to the underlying cause, Rosenthal suggests a degeneration of the sympathetic ganglia, citing, in support of this theory, the results of autopsies by Köhler, Demange, Landouzy, and Dejerine. Jürgens, in a case of grave secretory trouble of the stomach, found extensive degeneration of the plexus of Meissner and of Auerbach. Blaschko and Sasaki found similar lesions in cases of gastro-intestinal glandular atrophy.

From all that is known of the subject it is evident that, in any case, the gastric clinical phenomena are of less importance than the information to be derived from a careful study of the general condition of the patient, in order to determine the nature of the underlying neurosis—whether it is structural or functional, ataxic or neurasthenic. Lavage, and other local measures, to relieve the irritation present, may succeed in diminishing morbid reaction and in preventing some of the unfortunate sequelæ, but it is the neurosis which demands treatment, if cure is to be effected.

Marine-Hospital Service.—The present status of this service as a branch of the Treasury Department's work may be changed. It is stated that a movement is on foot to make the Marine-Hospital Service a department of the medical service of the navy.

REVIEWS.

The Throat and Nose, and Their Diseases. By Lennox Browne, F.R.C.S.E. Third edition, revised and enlarged. 8vo., pp. 716. Philadelphia: Lea Brothers & Co., 1890.

Mr. Browne's work on diseases of the nose and throat is to-day, probably, more widely used as a text- and reference-book than any other work on the same subject, and deservedly so, for it is the result of enormous experience and a critical observation of the practice of other laryngologists, and is almost absolutely free from dogmatism.

The chief change noticed in the third edition is that the chapters upon intra-nasal diseases are much fuller, one hundred pages being devoted to diseases of the nose and accessory cavities, beginning with an excellent chapter upon etiology. Mr. Browne attributes great importance to the cilia lining the respiratory tract of the nose in maintaining a healthy condition of the mucous membrane, and believes that destruction or injury of the cilia by smoke, irritating vapors, etc., is often the starting-point of a chronic catarrh.

In reviewing the causes of ozæna the author suggests that, in some cases at least, the condition is due to a congenitally imperfect development of the lining membrane of the nose, and that in such the tissues have at no time been able to perform their proper functions.

The entire subject of reflex diseases of nasal origin is very thoroughly discussed, and in a perfectly unbiassed spirit. The evidence is so logically stated that the most sceptical, after reading the pages devoted to this, cannot fail to be convinced that many diseases, and often those in which such a connection would not be expected, arise from some nasal abnormality, and can be cured in no other way than by intra-nasal treatment.

As to the etiology of chronic hypertrophic rhinitis, our author is fully in accord with the views of Dr. J. N. Mackenzie, namely, that the disease is the result of recurring attacks of acute and subacute catarrh; and he cannot agree with Bosworth, that septal spurs or deviations are factors, although admitting that their removal constitutes an important part of the treatment. In the treatment of hypertrophic rhinitis he thinks that sprays and douches are of little use, and that surgical measures must be chiefly relied upon. In cases uncomplicated by septal deformities the galvano-cautery will usually accomplish all that is desired; but in those which are not relieved by such measures, he has had encouraging results from the use of gelatin bougies formed on a rigid wire nucleus and medicated with iodol, chloride of zinc, etc. He thinks that paresis of the alæ nasi not infrequently prevents complete cure, and for the relief of this he advises the use of stimulating smelling-salts, menthol inhalations, and "gymnastic exercise of the nasal dilator muscles." In a few instances he has resorted to faradism. Unfortunately, he does not tell us why inhalations should relieve the paresis, nor how "alar gymnastics" can be performed.

Septal diseases—perforation, deviations, and hyperostosis—are thoroughly discussed, and clear directions given upon the operations indicated, and the proper methods of performing them. Mr. Browne is opposed

to Adam's operation of refracturing the septum for traumatic deviation, and believes that rectification can be secured by removing the obstruction by means of a saw or trephine. He writes enthusiastically of Curtis's nasal trephine, and considers it the most useful instrument devised for the relief of hard obstructions.

The least satisfactory portion of the work is that upon aural diseases, though even here there is much sound advice, and Mr. Browne shows that he is more familiar with otological work than are most laryngologists.

In the second edition of this book Mr. Browne was very distinctly opposed to the operation of intubation in laryngeal diphtheria. Now, however, he confesses that his former objections have been almost entirely dissipated, chiefly by observing the results of the operation in America.

In this brief sketch we have purposely confined ourselves to the points in which the third edition of the work differs from the second, and have necessarily passed by much that is valuable, but with which all laryngologists and many general practitioners are already familiar. In general appearance the treatise differs but little from the preceding editions, and, indeed, it could not well be improved in this particular. The binding is substantial, the type clear, and the illustrations—many of which are reproductions of Mr. Browne's drawings—are numerous and above criticism.

CORRESPONDENCE.

ORIENTAL MEDICINE.

To the Editor of THE MEDICAL NEWS,

SIR: Oriental medicine in the post-mediæval period has received so little attention in the study of the history of medicine, and the materials for research are so scanty, that I venture to think the recipes below may be of interest. They are written on the fly-leaves of the *Williams Codex*, the property of Mr. Robert S. Williams, of Utica, N. Y., and are the subject of an elaborate prolegomena by Dr. Isaac H. Hall, published by the Johns Hopkins University, in 1886, with *fac-similes* of the Syrian Antilegomena epistles which it contains. The translations of the prescriptions given below are, however, by Dr. Van Dyke, of Beirut, Syria. The extracts date, in all probability, from about 1471, the MSS. being dated July 4, 1471, and the prescriptions, in Arabic, being written at about the same time, and in Mesopotamia, probably near Husn Keifa. I dare say, most European physicians at the time would have deemed them useful, as they antedate Paracelsus and are contemporary with Campegius. "Steeped water of fresh glass" is, of course, a periphrasis for distilled water, and the day is still, I believe, in the future when the necessity for this precaution will be both accepted and acted upon by all our own apothecaries. TALCOTT WILLIAMS.

Recipe for the Philosopher's Electuary—they also call it "The Matter of Life." "It is useful in excess of phlegm, and strengthens the soul, and rejoices, and digests, and eructates, and appetizes, and increases the capacity to commit to memory and to remember, and acuteness of intellect, and loosens the tongue, and removes indigestions, and stops 'stillicidium urinæ,' and quiets flatulencies, and increases the seminal fluid, and strengthens the penis, and makes firm the teeth, and removes pains in the joints and back. It is made of pepper and long pepper, and myrobolans and Myrobolans Bellerica, and Amyros Zeilanica, and Aristolochia (roots), rolled, and male orchis, and twigs of chamomile, and heart of pine seeds (and) citron. To be pounded and sifted and moistened like other electuaries. The dose of it is about the size of a walnut, and God is the healer of all pains."

A trial of dentifrice composed of fennel (?). (Reading doubtful. The lines apparently not perfect.)

Electuary of assafœtida (benefits) from all stings of insects and quartan fever, and from . . . assafœtida, pepper, rue . . . to be pounded and sifted and mixed ("fiat massa"). The dose . . . removes . . .

(Much effaced, and words where . . . appears are obliterated.)

The dose of myrrh is half a drachm.

Talikûn. [No such word known in Arabic—probably a Mesopotamian corruption of Talcûn—Talc]: This vitriol (or alum) its scar will not granulate nor heal, and if with tweezers made of this vitriol (or alum) the hair be extracted, it will not grow at all, ever; and if a small hook be made of it, there will be caught a large fish; it debilitates it and makes it drunk; and if there be made of it a probe (*i. e.*, anything used for touching the eyes with stibium), and a sore eye be touched with it, it cures it; and it has, beside these virtues, high properties. It is made (thus): to be taken, zinc (calamine) prepared with hot water and steeped in the urine of cattle a long time, then taken out and dried, and to be taken some red coral and ground fine and steeped water of fresh glass next ten days, then taken out and dried, then all pulverized together. Then melt purified copper, and when melted in the crucible, inoculate it with the (above) medicine a times until it becomes cleansed. To every ten (parts) add two of the medicine.

To catch . . . take berries of solanum nigrum . . . bruise the leaves . . . and hang it . . . Another like it: take tartar and drug, and flour of barley and blood . . . equal parts; pound the whole . . . the place in which is . . . to it from every place, and if it is made . . . linen and let down to . . . the fish they can be caught with the hand. . . . Another, from Said el Hammam: Take horse beans and cook them with sulphur . . . and seeds of hyoscyamus niger, any bird . . . to the earth and does not (sit) high . . . take it by the hand, and if you wish pour oil . . . into its mouth.

NEWS ITEMS.

The American Association of Gynecologists and Obstetricians.—The American Association of Gynecologists and Obstetricians will hold its next annual meeting in Philadelphia, on Tuesday, Wednesday, and Thursday, September 16, 17, and 18, 1890, in the hall of the College of Physicians, corner Thirteenth and Locust Streets. All physicians interested are invited to attend the several sessions. E. E. MONTGOMERY, M.D., *President.*
W. WARREN POTTER, M.D., *Secretary.*

American Dermatological Association.—The fourteenth annual meeting of the American Dermatological Association was held at Richfield Springs, New York, September 2, 3, and 4, 1890. After a brief business meeting the President, Dr. Prince A. Morrow, delivered his address. Papers were read by Drs. R. W. Taylor, L. A. Duhring, R. B. Morrison, J. N. Hyde, J. C. White, H. W. Stelwagon, and others.

The American Orthopædic Association.—The fourth annual meeting of the American Orthopædic Association will be held at the College of Physicians, Philadelphia, September 16, 17, and 18, 1890. A large number of papers will be read, and the meeting promises to be an interesting one.

Mississippi Valley Medical Association.—The medical profession is cordially invited to attend the sixteenth annual meeting of the Mississippi Valley Medical Association, to be held at Louisville, Ky., October 8, 9, and 10, 1890. The President of the Association is Dr. Joseph Mathews, Louisville; Secretary, Dr. E. S. McKee, Cincinnati; Chairman of the Committee of Arrangements, Dr. I. N. Bloom, Louisville. Elaborate preparations will be made for the entertainment of visitors. Papers from the East are promised by Drs. Frank Woodbury and H. A. Hare, Philadelphia; Dr. John A. Wyeth, New York; Dr. William C. Wile, Danbury, Conn.; and Drs. Sutton, Daly, Wood, and Murdoch, Pittsburg. Papers are also promised by many other prominent men in the profession.

This Association is an outgrowth of the old Tri-State Medical Society, which comprised members from Indiana, Illinois, and Kentucky, and now includes all the territory in the valley of the Mississippi.

The interest of the occasion will be further increased by the annual meeting of the American Rhinological Association, which will be held in Louisville October 6 7, and 8.

The Reported Case of Cholera in London.—Regarding the case reported as one of cholera, in London, a note in *The Lancet* says that though the clinical symptoms point to Asiatic cholera, there would appear to be nothing incompatible with the diagnosis of severe so-called English cholera, or cholera nostras, cases of which are by no means uncommon in England during the summer months. Every possible precaution has, however, been taken in the interests of the public health. The vessel from which the patient came has been fumigated, and her water-tanks emptied and cleansed. The conveyances by which he travelled have been disinfected, while the house, clothing, etc., have been thoroughly fumigated and cleansed. The improbability of the case being one of Asiatic cholera rests on the facts that no other cases of a like nature have occurred on the voyage or since, although all clothing and effects in the possession of the patient had been used by him during the voyage; and, further, that he was in his ordinary health on arrival. A possible source of infection has been suggested in the wearing of a suit purchased in a Calcutta bazaar. It has, however, been proved that the suit was bought in London after his arrival. The patient is rapidly recovering.

Stramonium Poisoning.—Two children were poisoned in Philadelphia, September 5th, by eating the seeds of Datura Stramonium. One, a girl three years old, died in a few hours; the other, a boy of the same age, recovered.

Dr. Gray's Treatise on Nervous Diseases.—The many friends of Dr. Landon Carter Gray will learn with pleasure that the literary labor on his forthcoming work on *Diseases of the Nervous System* is drawing toward completion. Throughout it has been Dr. Gray's aim not simply to record that which is already known of this obscure class of troubles, but to add the increment of his personal experience and give to his work the impress of personal individuality that must add largely to its value.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 2 TO SEPTEMBER 8, 1890.

WOODHULL, A. A., *Major and Surgeon*—Is granted leave of absence for one month, on surgeon's certificate of disability, with permission to go beyond the limits of the Department.—Par. 1, *S. O. 122, Headquarters Department of the Missouri, St. Louis, Mo.*, September 5, 1890.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon.*—Is hereby granted leave of absence for one month, to take effect on or about October 20, 1890, with permission to apply for an extension of one month.—Par. 1, *S. O. 74, Department of California, San Francisco, Cal.*, August 30, 1890.

DE WITT, THEODORE F., *First Lieutenant and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect September 15, 1890.—*S. O. 76, Headquarters Department of Texas, San Antonio, Texas*, September 1, 1890.

APPOINTMENT.

BAXTER, JEDEDIAH H., *Colonel and Chief Medical Purveyor.*—To be Surgeon-General, with the rank of Brigadier-General, August 16, 1890, vice Surgeon-General Moore, retired from active service.—*Headquarters of the Army, A. G. O., Washington*, September 1, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 6, 1890.

WISE, J. C., *Surgeon.*—Detached from Torpedo Station, and ordered to the U. S. S. "Alliance."

FITZSIMMONS, PAUL, *Surgeon.*—Ordered to the Torpedo Station, Newport, R. I.

BRIGHT, GEORGE A., *Surgeon*—Detached from the U. S. S. "Constellation," and ordered to the Naval Academy.

OLCOTT, F. W., *Assistant Surgeon.*—Promoted to be Passed Assistant Surgeon.

WENTWORTH, A. R., *Passed Assistant Surgeon.*—Requests to withdraw resignation; granted.

CRAWFORD, M. H., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Monongahela," and granted two months leave of absence.

KEENEY, JAMES F., *Assistant Surgeon.*—Detached from the U. S. S. "Richmond," and granted two months' leave of absence.

LOWNDES, CHARLES H. T., *Assistant Surgeon.*—Detached from the Naval Academy, and ordered to the U. S. S. "Richmond."

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

HISTORY OF THE ADMISSION OF LIGHT IN THE AFTER-TREATMENT OF CATARACT OPERATIONS.

A Clinical Lecture,
delivered at the Charleston City Hospital, July 28, 1890.

BY MIDDLETON MICHEL, M.D.,

PROFESSOR OF PHYSIOLOGY AND MEDICAL JURISPRUDENCE IN THE MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA, AND ONE OF THE SURGEONS OF THE CITY HOSPITAL OF CHARLESTON, S. C.

GENTLEMEN: We shall select for our clinical remarks this morning the cataract operation performed several weeks ago upon this woman, sixty years old. After rendering the eye, instruments, and hands aseptic, and using a four-per-cent. solution of cocaine, the linear method was adopted, performing an iridectomy, removing the lens, then closing the eye with isinglass-plaster alone—a plan of dressing the eye which we have exhibited to our classes for several years. The patient was allowed to sit up in the open ward after the operation and to take her ordinary food, though she was not permitted to go into a bright light nor to smoke her pipe, both of which my assistant, Dr. T. S. Bratton, informs me she did in a few days.

I bring this case before you as one which might be termed a perfect result, for the conjunctiva and cornea are clear; there is a well-formed coloboma with no imprisonment of the iris; the pupil is clear; the linear cicatrix is of no great extent, and vision is good for objects at a distance. Out of this window she sees the lawn, and says that she sees some object crossing over the grass. With a two-inch cataract-glass she could doubtless thread a needle. When, however, the eye has undergone so severe a mutilation of its dioptric media, you should watch it with jealous care for weeks, before subjecting it to tests with proper glasses that will prove whether, indeed, you have met with perfect success.

An eye is necessarily hypermetropic after losing its lens, the removal of which destroys its power of accommodation also; if the dioptric apparatus, thus absolutely impaired even when the operation appears successful, is to be of any ultimate use to the patient beyond mere light-perception, it must first be rendered emmetropic for clear vision at a distance; and, secondly, must be rendered myopic for clear vision at 20 or 40 cm. from the eye. To ascertain what has been the result of your surgery, visual acuity must be tested with at least a 10 D. for the one purpose, and with about a 14 D. for the other. This must not be done on a feeble and injured eye for some weeks after your surgical intervention; therefore I desire to guard you against rushing with prurient haste into statements of statistical results until you are certain of the ultimate condition of this sensitive organ. During my service in the hospital last year, three patients entered whose eyes had been operated upon for the removal of cataract a few months previously. One of these eyes was in such a condition as to endanger its healthy fellow, and I was soon obliged to enucleate the ball. Another of the patients suffered from an irido-cyclitis of some months' duration and lost the sight completely, while the third patient went through iritic complications which, I doubt not, by this time have destroyed the sight.

Entanglement of the iris, after a cataract operation, may exist for some time before giving rise to iritis; a pupil perfectly clear on inspection may, after a short time, reveal a delicate floating fragment of wrinkled anterior capsule, so transparent as to be scarcely discerned, yet quite enough to interfere permanently with vision; and plastic lymph may be organizing into indestructible adhesions which, sooner or later, will surely ruin the results of the operation. Remember, that the size, direction, and depth of your incision, whether this be corneal, scleral, or corneo-scleral, almost always determine the subsequent result of your operation. The incision either avoids or leads to the production of cyclitis with the resultant contraction of the cicatrix and adjacent tissues; or perhaps yet more frequently to incarceration of the iris, which, if it do not involve the eye in panophthalmitis, may, even under the most favorable circumstances, cause chronic cyclo-iritis. An awkward incision is often succeeded by a flattened cornea, produced by a cicatrix that contracts, distorts, and occludes the pupil, dragging it toward the scleral border; and when defervescence of inflammation occurs, such an eye may retain a certain amount of vision for a while, but blindness eventually supervenes from the intra-ocular pressure caused by an abortive iridectomy, a detached retina, and a shrunken vitreous. Postpone judgment, then, respecting your supposed success until the patient uses glasses and can *see* with them.

I will not detail the steps of the operation which you witnessed the other day. I shall not inflict you, nor waste your time with the platitudes that are too frequently spread out in printed pages of redundant and battologized instructions—how to cleanse the eye, to hold the knife, to make the section, and to extract the lens. These things, by this time, you have seen so often, and concerning which you have read so much, that, with your present knowledge as graduates, you will only be the more ready to criticise severely should you discover me to be a delinquent respecting any of them. Nor shall I indulge in complacent dogmatism respecting any particular method that you should adopt in every case. With the knowledge and judgment which I presume you to possess, you will of course modify your methods according to the particular case. When you take up your keratome, "take no trenchant blade in hand" with dictatorial asseverations against iridectomy. At least let the names of de Wecker, Knapp, and others hold

your Delphic utterances in abeyance. Perform iridectomy when it is obviously indicated; occasionally leave the iris with its perfect pupil when this brilliant result can be effected; while in the aged, in whom the suspensory ligament is feeble or relaxed, extract the lens in its capsule, as you saw me do in this woman, so as to avoid the possibility of a secondary pupillary membrane. Indeed, gentlemen, eclecticism in surgery is a lesson which experience is sure to teach.

My object, however, on this occasion is to speak to you of the after-treatment of cataract operations without excluding light. I can give no offence to the historian of our professional literature in dwelling exegetically upon the open method of dressing the eye after the extraction of cataract, as I thereby will furnish you with such information respecting our varied methods of treatment that you shall not suppose that what you and others have seen me do is an innovation of my own.

Toward the end of the last century Daviel, a Frenchman, first taught us that a cataractous lens could be extracted through a large corneal flap; a most difficult and extremely delicate operation, attempted for many years after by only a few expert surgeons, for the eye became practically opened in half its corneal extent, and was therefore often evacuated—vitreous, lens, and all its contents—by sudden contractions of the recti muscles. After such a corneal section it was found absolutely necessary to place the eye in a specially secured condition against anything like spasmodic contractions, or even movements associated with those of the muscles of the opposite eye. It became requisite then to put the eye up in splints, so to speak; while it was on physiological principles equally important to prevent the other eye from roaming about, so as to check what we know constitutes the associated movements of the recti muscles of these organs. Therefore was it that both eyes were bandaged; and for the careful adjustment of compresses that could exert the minimum of pressure with the maximum of resistance to accidental, spasmodic, or associated movements of the eyes, every variety of appliances and bandages were invented from Daviel's to the popular bandage known as Liebreich's.

Again, the painful ingress of light which, of course, very naturally followed upon the first exposure of these organs for simple inspection after the operation, was found to be so distressing, oftentimes so intolerable, and even dangerous through sympathetic retinal excitation, that a darkened room, or bed inclosed by curtains, came to be resorted to; not that light itself was thought to be injurious, but its sudden entrance through preternaturally dilated pupils and impingement upon the now sensitive retina, excited reflex sympathetic trouble in the eye that had been operated upon.

It is very significant that as soon as Beer invented the well-known and well-devised knife that facilitated a safer and easier performance of the corneal-flap operation without escape of the aqueous, and that secured a more frequent cicatrization of the wound, that he himself became the first to advocate the introduction of light into the patient's apartment, and urged others to follow his example; but it was not until von Gräfe introduced his peripheral linear incision through the upper segment of the cornea, of such inconspicuous extent as to heal readily in a few hours or days, that so much danger was obviated, and so much more confidence felt in its performance even by the most inexpert, that the idea of disencumbering the eyes of heavy dressings, and of no longer enforcing precautionary measures against improbable accidents suggested itself.

It is a valuable thing to be possessed of an idea that rests upon a rational scientific basis; and that is carried out with patient, earnest, persevering conviction of its ultimate usefulness and success. The thought becomes so affiliated with one's nature, that the expectant results in their minutest details present themselves ever and anon to the mind until its accomplishment is theoretically and practically fulfilled. Such a predominant idea evidently occupied the mind of Walton while adopting his after-treatment of cataract. In his published record we find the method announced with the fulness of a completed achievement, and with every argument that justifies the method. So important are Walton's precise yet epitomized directions that I shall read them to you word for word from the *Medical Times and Gazette*, December 3, 1870. He says:

". . . . The first thing is to close the eyelids with a couple of strips of court-plaster about an inch and a half long and a quarter of an inch wide . . . . this insures adaptation and supports the corneal flap. . . . Such closure accomplishes all that can be done for the wound without disadvantage. . . . . The tears and the aqueous readily escape because some portions of the eyelids are uncovered. Bandages and compresses of all kinds are injurious. They are hurtful in proportion to their action. All pressure, beyond that which is naturally produced from closing the eyelids, must tend to be prejudicial, and at times to be positively damaging. Whatever keeps the eye hot must be bad—whatever soaks up the secretions is objectionable. I am well aware that some surgeons pack the eye with cotton-wool or charpie and subsequently apply a bandage. This system is like the French method of treating a stump after an amputation. I believe it to be important that the patient be well fed, and, therefore, I allow him a full diet. It is a mistake to prescribe liquid food under the idea that chewing is hurtful to the eye, for in man the muscles of mastication cannot in any way influence the eyeball. It is different in most of the lower carnivora."

Now, this was Walton's treatment in 1868–69, concerning which he goes on to say:

"I believe its simplicity is the chief reason why this—my practice—is not more generally followed. It leaves nothing for meddlesome fingers to do."

But Beer, as I have already said, opposed bandages and was in the habit of closing the lids by "*strips of sticking-plaster*," which he carried, however, down over the cheek. Beer was followed, as we could show, by many German operators; and all this was in 1801.

Lawrence, in his celebrated lectures delivered at the London Ophthalmic Infirmary, and published afterward in the *Lancet*, October, 1825, p. 145, objects to bandaging the eyes, and writes:

"The application of a bandage to the eye is not to be regarded as an essential point of treatment; it is rather employed to keep the eye quiet and to guard it from any slight accident. On this account gentle confinement during the night is expedient; but the part may be left

uncovered, or with a damp rag over it, while the patient is awake."

Lawrence states, also, that:

"Mr. Tyrrell has suggested that when the patient has the advantage of a good attendant, he might remain for a few hours on a couch or easy chair; so that he will be less likely to fall asleep than in bed, and thus have a better chance of sleeping at night."

The most liberal praise must, however, be awarded to Walton, whose practical injunctions on this subject more particularly arrested the attention of oculists, though receiving, perhaps, scarcely deserved prominence until Wilde, of Dublin, confirmed these teachings and practice. It was from Wilde that our own lamented friend, the late Dr. C. R. Agnew, obtained his knowledge respecting this treatment, and adopted the same in his own practice. Writing to me in July, 1885, in the letter which you here see, Dr. Agnew refers thus to this important matter:

"In the proceedings of the American Ophthalmological Society for 1869 you may find a paper by your humble servant, with the title 'A method of dressing eyes after cataract extraction and other ophthalmic operations requiring rest by exclusion of light.' In that paper I take ground against shutting patients in the dark. In founding the Brooklyn Eye and Ear Hospital, in 1868, provision was made to provide light in the wards. The same was true and continues to be so in the case of the Manhattan Eye and Ear Hospital, opened in 1869. Both these hospitals are as light as any other hospital that I have seen. I have taught in the College of Physicians and Surgeons for more than twenty years against incarcerating eye patients in the dark."

The merits and advantages of so beneficent a release offered to cataract patients were not long withheld from American surgeons who keep abreast with the progress of their science. So we find that in Philadelphia Drs. Levis and Roberts at once acknowledged the importance of such a course, and for years have followed no other in the Pennsylvania and in the Wills Eye Hospital. Since the establishment of an Ophthalmological Department in the Jefferson Medical College Hospital, in 1877, Dr. Thomson also has banished the proscriptive measures usually enforced under such circumstances. The American editors of the fourth edition of Stellwag's *Diseases of the Eye*, 1873, on page 641, say:

"The discussion in this country of the subject of cataract and its treatment being an almost everyday occurrence, American surgeons have been led to modify materially the after-treatment. The patients are not confined to their beds so long as formerly, and surgeons are not so particular in excluding every ray of light. A few turns of a flannel roller-bandage, or even a piece of black silk placed over the eyes and retained in position by strips of adhesive plaster, is all that is ever used, and then the room is moderately darkened for several days."

The same course has been adopted for years by many oculists; thus we are informed that Dr. Charles E. Michel, of St. Louis, has for eighteen years pursued a like plan, and has published his reasons in its favor. Dr. Joseph A. White, of Richmond, Va., in his annual report of the work done at the Eye, Ear, Throat, and Nose Infirmary, refers to the success of dressing with goldbeaters' skin, after Dr. Michel's plan, in favorable cases and in docile patients. Impressed with the results of Dr. Michel's practice, Dr. Chisolm, of Baltimore, has been recently induced to give the method a trial.

I could furnish exhaustive proof by an unbroken web of evidence of the value of this method of after-treatment did time permit; but enough has surely been said to rectify any misapprehensions as to the source whence we have derived our knowledge of this simple, soothing, beneficent, and defensible method; and it only remains to recommend it highly to your attention, not only for its intrinsic value in almost every case, but for the avowed popularity it has attained both in Europe and America. Isinglass and rubber strips, undarkened apartments, and freedom from restraint in the management of cataract and iridectomy operations, are not now under trial for the first time among ophthalmologists; the names of Walton, Wilde, Lawrence, Tyrrell, and Agnew will assuredly permit you to take their counsels in this matter safely "on trust;" in resorting to it, then, in your future practice you will not be treading upon doubtful ground, and will not have to watch with anxious solicitude lest some untoward accident should befall your patient.

ORIGINAL ARTICLES.

SURGERY OF THE LATERAL VENTRICLES OF THE BRAIN.

Résumé of Paper read before the Surgical Section of the Tenth International Medical Congress, Berlin, August, 1890.

BY W. W. KEEN, M.D.,
PROFESSOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA, PA.

AFTER alluding to the fact that puncture of the brain for the relief of hydrocephalus dates back to the case of Dean Swift in 1744, Dr. Keen pointed out that the early operations were done through the anterior fontanelle, and not by trephining. In 1881 Wernicke first proposed to trephine and puncture the lateral ventricles. This proposal was adopted by Zenner, of Cincinnati, in 1886.

On November 7, 1888, Dr. Keen read a paper before the College of Physicians of Philadelphia,[1] in which, in ignorance of these earlier propositions, he proposed to trephine, puncture, and drain the lateral ventricles. The idea was suggested to him by a case of exploratory trephining for supposed abscess in the temporo-sphenoidal lobe. The post-mortem examination showed that there was distention of the lateral ventricle in consequence of tubercular meningitis, and that the drainage-tube had reached to within a quarter of an inch of the ventricle without producing inflammation. He pointed out the fact that the brain would not bear pressure nearly as well as the other viscera, and hence the need for early trephining. He then reported the following three cases of his own.

CASE I.—A boy, four years old, was threatened with blindness from acute hydrocephalus. This

[1] THE MEDICAL NEWS, December 1, 1888.

condition was thought to be due probably to tumor of the cerebellum, though on which side was doubtful. Dr. Strawbridge had examined the eyes and had found that there were choked disks with retinal hæmorrhages and swelling. The swelling of the disk measured 2.30 mm. in each eye, and in view of the rapidly-increasing blindness he brought the child to Dr. Keen for operation. This was done at the Woman's Hospital, Philadelphia, January 11, 1889.

A puncture was made at a point one inch and a quarter behind the left meatus and the same distance above "Reid's base-line." A half-inch button of bone was removed and the brain punctured by a hollow needle (No. 5 French catheter scale), which was directed toward a point two and a half inches vertically above the opposite meatus. At a depth of about an inch and three-quarters the resistance suddenly ceased, and the cerebro-spinal fluid began to escape. Three stout doubled horsehairs were then passed into the ventricle. No peculiar phenomena occurred during the operation. The highest subsequent temperature was 101⅔° for a brief interval, but most of the time it was normal. In two days the swelling of the optic nerves had fallen to 1.57 and 1.63 mm. in the right and left eye respectively, and by the sixth day to 1.09 mm. in both eyes. By the seventh day the swelling of the optic nerve had increased, and the drainage was not very free. The tumor was sought for by probing through the drainage-opening into the occipital lobe, almost to the occipital bone. No tumor being found by this procedure, an opening a quarter of an inch in diameter was gouged in the occipital bone below and to the left of the inion. The cerebellum was explored by a probe to the depth of two and one-quarter inches in the direction of the left lobe, and again obliquely across into the right lobe, but no tumor was found. This wound healed by first intention without any fever.

On the fourteenth day the horsehairs were removed and a small rubber drainage-tube was inserted into the ventricle in order to give free vent to the fluid. This was attended by no pain or discomfort. By the twenty-eighth day the child had become somewhat restless, and the swelling of the disks, which had fallen to 0.83 mm., had again increased to 1.33 mm. in each eye. Accordingly, the right side of the skull was trephined at the corresponding point above and behind the ear, and the occipital lobe was punctured to the tentorium, but no tumor was found. A drainage-tube was then passed directly into the right ventricle, being inserted without the prior puncture by a hollow needle.

On the thirty-second day, by a fountain-syringe, the bag of which was raised about six inches above the head, the ventricles were irrigated from side to side with warm boric acid solution—4 grains to the ounce. While the connection was being made with the tube the child was a little restless, but so soon as the warm water began to flow into the brain he became quiet and said that "it felt good." The fluid slowly escaped from the opposite side. The bag of the syringe was then elevated until the escape became quite free, but not a continuous stream. It was estimated that about eight ounces passed into the ventricles, of which about two ounces escaped from the opening on the opposite side, consequently about six ounces were retained. No phenomena whatever were apparent during the process described except the comfort shown by the child.

On the thirty-fourth day the ventricles were again irrigated from side to side with plain boiled water, which gave less relief than the boric acid solution, but produced no ill effects. A few days later the child was evidently not so well, and he died on the forty-fifth day, the first drainage-tube having been in place nearly continuously after the operation.

At the autopsy the cerebro-spinal fluid was found perfectly clear, more so than that obtained at the first tapping, which was slightly turbid. The ventricles were greatly distended with fluid. In the left lobe of the cerebellum a sarcoma was found, which had compressed, as had been suspected, the straight sinus and the veins of Galen, and had encroached upon the fourth ventricle. The sinuses through which the rubber tubes passed were not surrounded by an inflammatory zone. There was no injury of the opposite wall of the ventricle, and no trace remained of the punctures in the cerebrum or cerebellum. The oblique puncture made in the latter had gone through the tumor, which, however, was too soft to be perceived at the time.

Case II.—A boy, aged three and a half years. Hydrocephalus set in four or five months after birth. His mental condition was extremely weak.

On March 5, 1889, the left ventricle was tapped in the same manner as in Case I. At a depth of an inch and a quarter the resistance suddenly ceased, and the cerebro-spinal fluid immediately escaped. As in the first case, the fluid was slightly turbid. Drainage by horsehairs was in this case also not very effective. The highest temperature after the operation was 100⅖°, and there was marked increase in the use of the right arm, which had been paretic. The drainage being insufficient, on the fourth day the ventricle on the opposite side was opened, and a small drainage-tube inserted in each ventricle. These were stopped by disinfected plugs of wood, with a V-shaped slot cut in each, so as to permit the escape of the fluid at the rate of about thirty-five drops a minute. As this seemed to be too free, after four and a half hours other disinfected plugs were inserted with smaller slots. Convulsions began the next day, and when Dr. Keen reached the patient he found the convulsions constant. He then decided to replace the fluid that had been drained away, and having no time for the preparation of an artificial cerebro-spinal fluid, he used plain boiled water for this purpose. This was siphoned from a height of about eight inches. When the warm water began to flow into the ventricles the spasms ceased. The flow was then immediately stopped by squeezing the tube, and in a few minutes the convulsions returned. They were immediately arrested again by allowing the water to flow. Eight times the convulsions returned and each time they were arrested by a siphonage of from half an ounce to one ounce of fluid. Dr. Keen estimated that the amount of

fluid injected was nearly a pint. No further spasms occurred, but the child gradually failed, and died in the afternoon. The post-mortem showed great hydrocephalic distention, but no injury from the operation.

CASE III.—This was a case of tubercular meningitis, with unilateral acute internal hydrocephalus of the left ventricle. The foramen of Monro, as determined at the autopsy, was closed. This closure was attended by unilateral distention, and produced right hemiplegia. In this respect the case is probably unique. The left ventricle was tapped through the arm-centre. The child was almost *in extremis* when the operation was performed, and died about four hours later. At this operation also it was easy to determine when the ventricle was reached.

Dr. Keen next referred to the case reported by von Bergmann in his *Surgical Treatment of Brain Lesions*, as the first case ever operated upon, though not published until after the reader's paper and a note upon his first case. Von Bergmann's case was operated on, July 15, 1887, by the anterior route, and proved fatal on the fifth day. Dr. Keen then described two cases reported to him by letter by Mr. Mayo Robson, of Leeds, as follows:

A girl ten years old, without preceding illness, began to have pain in the left ear, and was feverish, December 19, 1888. In three days a discharge followed, which gradually lessened, but was still present a month later when admitted to the hospital. There had been also rigidity of the neck and twitching of the right angle of the mouth. No vomiting; slight mental disturbance. On admission, January 19, 1889, her temperature was 105°; she complained of pain in the left side of the head; there was paresis of the right arm and leg which gradually developed into complete hemiplegia and aphasia. Optic disks inflamed.

Operation, February 7, 1889: Trephining was done over the arm-centre; the dura was found healthy. On exposing the brain it did not pulsate, and seemed to be compressed. An exploring-needle was passed deeply in various directions in the hope of reaching pus, but failing to find any the needle was pushed into the lateral ventricle and a half-ounce of clear fluid was drawn off. After this, pulsation returned in the brain. The wound was closed as usual, no drainage being employed.

On the next day there was slight power in the arm, soon after in the leg, and on the third day she could answer simple questions. Within a month the hemiplegia was gone, and six months later she was perfectly well.

Even a half-ounce of fluid seems to have imperilled life by pressure, and the operation undoubtedly saved the patient's life—a most important and encouraging lesson for the future.

Mr. Robson's second case was one of an infant who was trephined for rapidly-increasing hydrocephalus, following treatment of spina bifida by Morton's injection. The skin was trephined an inch in front of the Rolandic fissure over the second frontal convolution. The dura was opened and the needle of an exploring-syringe inserted into the ventricle, which was reached an inch from the cerebral surface. By means of Lister's sinus-forceps a rubber drain was inserted, following the needle as a guide. The drainage was so free that it wet the dressings and ran on the floor, and after this the patient seemed much relieved. The drainage soon became less free, and on the third day the child died in convulsions. The post-mortem showed that the brain had shrunk so much that the end of the tube was lying between the dura and the brain.

Dr. Keen then referred to the case of Ayers and Hersman, in which, on December 4, 1888, puncture was made over the coronal suture an inch and a half from the middle line. The operation was repeated on April 28, 1889, by Dr. Hersman. The first operation was followed by the escape of from four to eight ounces of cerebro-spinal fluid, which caused evident improvement. At the second operation no fluid was found in the ventricle, and the child was very much improved.

Of the 7 cases thus far reported, 2 have recovered and 4 died—a mortality of 71 per cent., which, for a new operation, and for so extremely a dangerous condition, is far from discouraging.

Dr. Keen then entered into the question of the technique of the operation, and pointed out that it was not difficult or dangerous, and that the rules that he had laid down in his former paper[1] had proved to be correct, and that in his judgment the lateral route is the best, except in special instances. From his experience in these three cases he urges that the puncture be made by a canula (No. 13 French catheter scale), and that the drainage shall not be secured by a tube, but by a sufficiently large bundle of horsehairs, and that too much haste shall not be used in draining off the fluid, as such haste may cost the life of the patient, as in Case II.

The speaker then took up the question of hæmorrhage into the ventricles, and referred to the following case, reported to him personally by Professor Frederic S. Dennis, of New York. It is the first case in which a clot has been removed from the lateral ventricle.

A man, aged thirty-six years, was struck on the right side of the head by a falling ladder, but was not rendered unconscious by the blow. An hour after admission to the hospital his left arm became paralyzed, and later, the face and leg also. A diagnosis of cerebral hæmorrhage was made, and six hours after the accident he was operated upon.

A linear fracture without depression was discovered, and trephining was done over the arm-centre. No epidural and no subdural clot was found, nor was any clot discovered when the brain tissue was incised. Accordingly, an incision was made directly into the ventricle, and when the retractors were slightly separated a blood-clot about the size of a pullet's egg shot out of the ventricles with enough force to fall several feet from the patient's head.

[1] Loc. cit.

Gentle irrigation and drainage were used, and the wound was dressed in the ordinary manner. The patient never recovered from the paralysis, became delirious, and in three days died comatose.

The autopsy confirmed the diagnosis, and also showed that there had been great laceration of the cerebral substance, to which fact death was due. There was no meningitis and no suppuration.

The author then narrated four cases of abscess bursting into the lateral ventricle, beginning with the historic case of Detmold, in 1849, and adding three cases: one of Pancoast's, one of Morehouse's, and one of Morton's. All of the cases died, a result that would be expected after so serious an accident.

The next class of cases mentioned was that due to rupture of the ventricles by compound fracture. Two cases were referred to, one of Massa's, the other of Hewitt's, in each of which the lateral ventricles were primarily torn and there was free discharge of cerebro-spinal fluid. Both of these cases recovered.

Of secondary opening of the ventricles he mentioned seven cases, reported by Bouchacourt, Berenger de Carpi, Erichsen, Rodenstein, Cheever, and himself. Strange to say, four of these seven cases recovered.

Five cases of rupture of the lateral ventricles, from simple fracture of the skull, were also referred to, one each described by Thompson, Haywood, and Erichsen, and two by Lucas. All of these cases were in young children, five years of age or less, and all showed secondary soft swelling under the scalp. The cerebro-spinal fluid was removed, either by tapping, or, as in one case, by rupture. Of the five cases three recovered.

After consideration of the entire subject the following conclusions were reached:

1. Injuries involving the ventricles, the result of compound fracture or of trephining, and involving great disturbance of the cerebral substance, are not necessarily fatal, for ten of the twenty-six cases here reported have recovered. In these few cases compound fractures and extensive injuries, unless primarily fatal, seem to be less dangerous than rupture of the ventricle from simple fracture. They should be treated antiseptically by drainage and the usual treatment of wounds in other regions. If pus follows, or if the cerebro-spinal fluid becomes dammed back, causing symptoms of pressure, incision and free drainage should be resorted to.

2. In cases of simple fracture involving the ventricles, experience would seem to indicate that it would be wise not to attempt any operative procedure unless threatening symptoms supervene. If necessary to interfere, the cyst containing cerebro-spinal fluid should be continuously and slowly drained by a small bundle of horsehairs, rather than by freer evacuation. In the majority of cases constant pressure, and but little active treatment, may be all that is necessary.

3. Abscess of the brain bursting into the lateral ventricle has been thus far uniformly fatal, and demands the promptest treatment possible. The suggestion made for immediate bilateral trephining and irrigation of the ventricles can, at least, do no harm, although the possibility of its doing good is but slight in so serious a condition.

4. Hydrocephalus, whether acute or chronic, is usually a fatal disease. Surgical procedures for tapping the ventricles for its relief are easy, and certainly do not *per se* involve great danger. Whether they will cure the disease is, as yet, not determined.

5. In acute effusions, tapping, with or without drainage, as may be thought best, will certainly save some lives otherwise doomed to be lost; and, in the chronic form, long-continued slow drainage at an early period is at least worthy of a trial, with a reasonable hope of success in a few cases.

6. The methods here described for performing the operation, especially by the lateral route, are at least worthy of a trial, with a view to determine the value of such surgical procedures.

7. After trephining and tapping the ventricles, irrigation of the ventricular cavities from side to side is not only possible, but it does no harm. In abscess involving the ventricle, and possibly in other conditions, it may possibly do good. The fluid used for such irrigation should not contain anything which, if retained and absorbed, might do harm. An artificial cerebro-spinal fluid, or a simple boric acid solution, would seem to be the best for such use.

8. Convulsions, due to too rapid withdrawal of the cerebro-spinal fluid, may be checked by injecting an artificial cerebro-spinal fluid, or such other innocuous fluid that is available.

9. In either irrigating or injecting the ventricles it is probably desirable that the air should not enter, but such entrance of air does not seem to be productive of mischief.

10. In hæmorrhage into the lateral ventricle, at least of traumatic origin, immediate trephining and evacuation of the clots should be done, which in a few cases will probably be followed by a cure, unless the injury of the cerebral tissue is so great as to be incompatible with life.

THE SO-CALLED MOUNTAIN-FEVER OF COLORADO AND ADJACENT REGIONS, ITS DESCRIPTION AND TREATMENT.

BY L. HUBER, M.D.,
OF ROCKY FORD, COLORADO.

IN Colorado it is very common to hear the term, mountain-fever, both from the laity and from physicians. The term is not confined, however, to this

State, but is used more or less throughout the whole Rocky Mountain region. It will be interesting to know just what type of fever is meant by this, and its probable etiology, symptoms, and successful treatment.

Types of fever vary with diversities of climate, soil, altitude, etc. I am quite certain that I first observed cases of the so-called mountain-fever in the Arkansas River valley, in western Kansas. There it was not known by the above appellation; nevertheless, several years' experience with the disease convinces me of its identity with mountain-fever. In 1884 and 1885 there was rapid occupation and settlement of new lands in the vicinity of Kinsley, Kansas, where the writer was then in active practice. During these years there was an exceptionally heavy rainfall. Farmers were encouraged, vast tracts of prairie were converted into farms, and cities and towns were built. In this rush after homes and business little attention was paid to the source and quality of the drinking-water, a pool, or stream, or shallow well supplying it. The result was that many communities were fever-stricken. After the first extensive outbreak isolated cases continued to appear, and may occasionally be found at the present time.

In 1887 I removed to Rocky Ford, Colorado, a small town, 4100 feet above sea-level. Here, too, under the development of the irrigation system of agriculture, a rich valley was being rapidly converted into a farming country. The Arkansas River, the only stream or body of water in the vicinity, flows in a well-defined channel, and with a strong current. The current is also strong in the several irrigating canals, and there is no stagnant water from which effluvia would be expected to arise. Water was freely distributed over the newly-cultivated soil. The supply of drinking-water was drawn from the open ditches, filtered more or less thoroughly, and stored in cisterns. When carefully filtered and kept in clean reservoirs the water is clear and tasteless, and develops no odor for many months, if at all. It is, however, "hard," and is called *alkali* water.

Even in the mountain districts the same system of irrigation and water-supply exists, and the same types of fever prevail. The soil of the valley is a sandy loam, very rich and productive. The natural grasses of the valley are rather sparse, and the timber-belt is confined to narrow limits along the Arkansas.

With our previously conceived notions of the origin of malarial poison, it is difficult to believe that the fever in question is of malarial origin. A dry, almost rainless climate; a dry soil, sparsely covered with vegetation before the introduction of agriculture; an elevation of 4100 feet above sea-level, no marsh lands, and no stagnant waters—the very opposite to countries where we usually find the malarial poison. Yet, some eminent authorities recognize that the agent producing malarial fever is found under these circumstances. Professor Bartholow, in his *Practice of Medicine*, in defining the limits of malaria, says: "One important factor is elevation, malaria not breeding higher than 5000 feet above the sea, which seems to be its maximum limit. The apparent exceptions to this, afforded by the so-called 'mountain-fever' of Colorado will be alluded to hereafter." The same writer also observes: "That malarial poison is soluble in water, and is contained in the surface-water of infected districts, seems now to be well established. The author found the surface-water of Kansas to produce malarial fevers and cholera." Yet, withal, it is not difficult to find physicians of large experience who will deny the malarial origin of mountain-fever. As for myself, I have seen well-defined ague in persons who have not been away from the vicinity of Rocky Ford for a number of years. These cases were certainly contracted there. I have also met with typical remittent fever. These are not classed with the form of fever usually known as mountain-fever.

The description of several cases taken from the writer's note-book will prepare the way for a correct description of the disease, and perhaps furnish a true picture of it:

CASE I.—Walter B., aged twenty-one years; usually strong and healthy. He had been complaining for a few days, when, on April 9th, was taken with a chill, followed by high fever, headache, pain in right groin and in back and limbs. He was much depressed, and quite weak. I saw him on April 10th, and found the above symptoms persisting. Temperature 102°: pulse 100, and rather feeble. He had had several large watery stools. Tongue was rather heavily coated, but the tip was bare and red.

I ordered the following:

R.—Aromatic sulphuric acid . . 2 drachms.
Infusion of digitalis . . 2 ounces.
One teaspoonful every three hours.

Also:

R.—Sulphate of cinchonidine . . ½ drachm.
Extract of cascara sagrada . 6 grains.—M.
Divided in six capsules, of which one was taken every three hours.

I also directed a milk diet to be employed.

April 10. Morning temperature 103.5°; pulse 105: no nausea: no delirium: skin moist; bowels moved once during the day. Treatment continued.

11th. Morning temperature 101.5°; pulse 90, and strong. In the evening the temperature and pulse were unchanged. Patient has taken three pints of milk, and without discomfort. Treatment continued.

12th. Morning and evening temperature 99°; pulse 85. Headache and pains entirely gone. Tongue cleaning; patient feels stronger.

From this time he continued to convalesce; but

from the time required it was evident that the disease, even in its short course, had made quite a profound impression on his system.

CASE II.—J. H. G., adult; strong, and of a full habit; had been working on an irrigating canal for several days, and drank water therefrom. He had had slight diarrhœa, and felt weak. In the night he was taken with chills and diarrhœa; severe headache and pains in back and limbs. The stools, he says, were fœtid and ochre-colored.

On examination I found the temperature 102°; pulse 83. There was perceptible enlargement of spleen, and some tenderness over the abdomen. Patient's face was congested, and the eyes quite injected. I ordered the following:

R.—Sulphate of quinine . . . 5 grains.
Sanguinarine . . . . ¼ grain.—M.
To be taken at night.

Also:

R.—Dilute hydrochloric acid, } of each 2 drachms.
Glycerin, }
Water sufficient to make . . 2 ounces.
A teaspoonful every three hours.

A milk diet was ordered.

On the evening of the following day I found my patient quite comfortable; tongue cleaning; pulse and temperature normal. I ordered a dessert-spoonful of elixir calisaya after meals, and dismissed the case.

CASE III.—Richard D., aged seven years; taken on the night of April 5th with a chill, and severe pain in the gastric region. I found him with a temperature of 104°; pulse 120, and small; tongue coated, with the papillæ prominent; tip red and strawberry-like. The child was in great pain.

I directed warmth to be applied to his feet and limbs, and gave him two-drop doses of fluid extract of gelsemium every hour until the skin became moist, and the pain somewhat relieved.

April 6. At 7 A. M. patient much the same; temperature 104.5°; pulse 128; some delirium; headache; pain in spine and in back of neck; nausea and vomiting. Can discover no tenderness over the spine. The coldness of the extremities has disappeared; bowels are confined. I ordered the gelsemium to be continued in two-drop doses every two hours, and also one grain of calomel every two hours until five doses were taken. For the thirst I allowed an effervescing draught. Tepid compresses were employed to reduce the high temperature.

7th. Patient passed a restless night, the fever at times rising above 105°; pulse 130; is nervous, and tosses about in bed; headache still present, and uneasy sensations along the spine are complained of. Vomiting has ceased, and the patient retains milk. No tenderness along the spine. During the day the temperature fell more than a degree. No evacuation from the bowels. Pupils contracted. The gelsemium and the tepid-water compresses were continued. I ordered 5 grains of sulphate of quinine by the rectum every three hours.

8th. Temperature 104° at 6 A. M.; pulse 120; patient lies with arms flexed and rigid; stupor; pupils dilated. The bowels acted freely during the night; some tenderness along the spine, especially over the upper vertebræ; movement of the limbs causes pain; no vomiting; thirst considerably abated. Mild counter-irritation along the spine was ordered; quinine discontinued.

9th. Temperature 103°; pulse 114; patient sleeps naturally at intervals, and wakens less delirious; coughs considerably at times; takes milk freely at regular intervals; bowels have acted twice; tongue moist, and coated toward the tip; raised in flakes. Treatment continued.

10th. Temperature 103°; pulse 105; patient comfortable and rational, and takes milk freely. Expression good; changes his position readily. At 3 P. M. his pulse fell to 101.2°; pulse 96, and compressible; still coughs considerably. At 6 P. M. he was sweating freely, and passed a large quantity of urine. Later, his temperature became normal, and he slept well.

From this date there was slow convalescence, though on alternate days, for some time, mild fever appeared. With the administration of the following mixture, to which I am very partial under certain circumstances, the patient recovered:

R.—Dilute nitric acid . . . 1 drachm.
Sanguinarine . . . . 1 grain.
Glycerin . . . . . 3 drachms.
Water, sufficient to make . 2 ounces.—M.
One teaspoonful three times a day.

This case is rather typical of the disease in children, and my note-book could furnish other very similar examples. They all show the profound impression made upon the spinal cord and brain.

Symptomatology.—From these and similar cases the history of the disease may be sketched as follows: The premonitory symptoms are usually a chill, or chilly sensations, followed by fever more or less marked and persistent. The temperature ranges from 102° to 105° at the onset, but usually falls several degrees during the first week. There are no uniform or marked remissions, but, often, intermissions will follow the onset, and continue for a week, if the case is untreated, when the fever will return and assume a continued type, lasting from two to four weeks. There are often localized pains, and especially in children there is severe distress in the gastric region. The head, back, and limbs usually ache. These symptoms often very closely simulate those of spinal meningitis, as the above reported cases show. In adults the tongue is coated, excepting the tip, and sometimes the edges. A clean tip is always seen in cases that ultimately assume the typhoid type. In children the enlarged papillæ project through the coating, and the tip of the tongue is strawberry-like. The pulse and temperature usually preserve the normal ratio; if not, the former is rather slow. There are often nausea and vomiting, though these do not generally persist. The bowels may be loose or confined. In children

they are often stubbornly constipated, and difficult to regulate with medicines. The liver and spleen are frequently perceptibly enlarged. As a rule, there is no tenderness in the right iliac region, though this and a tympanitic condition sometimes arise.

The headache is often excruciating. Delirium is not usual, but when it exists it is low and muttering. The spinal symptoms are often marked, and consist in shooting pains passing up and down the spine and into the extremities. There may be tremor. Sometimes the patient loses the power of motion.

In not a small percentage of cases cough and bronchial irritation are present.

The eyes are usually suffused, and show slight signs of jaundice. In children the pupils are widely dilated. The skin is generally dry, sweating occurring only as the fever abates. Often the disease breaks up with a copious sweat and several free evacuations from the bladder and bowels.

Convalescence is slow and accompanied with a strong tendency to the development of a mild but obstinate intermittent fever, quotidian in type. Relapses are apt to follow at the septenary periods, unless the case is closely watched and carefully treated.

Treatment.—Having already specified the measures and remedies available in this disease, it would seem that little more need be said regarding the treatment. However, with a riper experience and wider observation I am constrained to speak in very positive terms on this subject.

The first proposition is that this so-called mountain-fever tends, under favorable circumstances, to pursue a benign course, but this does not signify that treatment is useless. By proper nursing, dieting, and medication, the disease can be shortened, and the suffering of the patient greatly mitigated. Baths are very useful, and should be systematically given. The temperature rarely rises to the danger-point, yet, for the harsh, dry skin, sponging with tepid water is effective. In children, when the temperature reaches the highest point, I direct tepid-water compresses to be applied over the abdomen and thighs. These often abstract enough heat to cause a perceptible fall in the temperature. For the hot, throbbing temples cold applications often add greatly to the patient's comfort.

The diet is not to be overlooked. I almost invariably order several ounces of milk to be given every three hours. It is not often that this regimen disagrees. When I find some contra-indication or some obstacle to its use, I order broth or some good beef-extract. The reason that I insist upon a fluid diet is that the bowels are already loaded, and slow to respond to medicines. When diarrhœa exists absorption is so interfered with that only the most assimilable foods enter the system.

The patient having no appetite, it will not do to consult his preferences and leave him without sustenance, or allow hurtful articles to be given. A due allowance of cold drink contributes greatly to the patient's comfort and welfare.

As to medicines, there are several that do positive good. Gelsemium, in from two- to five-drop doses of the fluid extract every three hours, will frequently control the fever, mitigate the spinal pains, and break up the disease. I have tried it alone in many cases, and with very uniform results. Even after quinine had been employed without satisfactory results gelsemium produced good effects.

The mineral acids, nitric or hydrochloric, or a combination of the two, are also useful. It is usual with me to employ a combination of the acids and gelsemium.

As to the use of quinine and its congeners, for some reason they are not satisfactory. They will check the disease, but they are slow in producing their effect, and in the high altitudes where this fever is found they cause an untoward impression on the whole nervous system. Usually there is more or less pulmonary congestion, and the quinine increases this. It requires large doses of the remedy to produce any early result.

After convalescence is established the septenary periods must be watched. It is always well to continue some mild antiperiodic for two or three weeks.

For isolated symptoms and complications the usual measures employed in other fevers are admissible. It is useless to try heroic measures to regulate the fever. In some regions it is customary to attack it with ponderous doses of mercurials and quinine, but the complications that then arise in the nervous system become serious. As hitherto remarked, the fever tends to self-limitation, but when thrown out of its course seems to take a firmer hold upon the patient, and to be more grave. On general principles it may be said that medication should be directed primarily to the maintenance of open emunctories and the elimination of the *materies morbi* through them.

THE SURGERY OF THE THYROID GLAND.[1]

BY A. H. LEVINGS, M.D.,
OF APPLETON, WISCONSIN.

THE thyroid gland, like the spleen and the thymus and suprarenal glands, has no duct. Its function is not well understood.

In its normal condition it is described as consisting of two lobes situated on the sides of the trachea, and connected by an isthmus which overlies the second and third rings of the trachea.

In its histological structure (Schenk) it is com-

[1] Read before the Wisconsin State Medical Society, June, 1890.

posed of connective and elastic tissue so interwoven as to form numerous meshes in which are found closed vesicles. These vesicles consist of a homogeneous membrane, lined with cylindrical epithelia and filled with a clear albuminous fluid. The cylindrical epithelia are often found detached and floating in the albuminous fluid, or forming small aggregations in different parts of the vesicles. A fine meshwork of blood- and lymph-vessels surrounds each vesicle. The nerves supplying the thyroid are derived principally from the sympathetic, but also to some extent from the pneumogastric.

Although the thyroid in its normal condition has but two, or at most three lobes, one on each side of the trachea, and the third, the pyramid, connected to the isthmus, in its pathological state, associated, connected or disconnected lobules are sometimes found. These associated lobules are in form and consistence not unlike the lymph-glands. They are situated, according to Wölfler, in the space bounded below by the arch of the aorta, on the sides by the carotids, and above by the hyoid bone. Gruber divides the accessory thyroid glands into superior, inferior, and posterior. The first two groups he further divides into median and lateral. The superior are those lobules found between the upper edge of the thyroid isthmus and the hyoid bone. The lateral glands or lobules are those found between the hyoid bone and the clavicle, generally situated near or associated with the lateral lobes. Of especial interest are the posterior accessory glands, found beneath the thyroid, between the trachea and œsophagus or below the œsophagus.

The enlargement of the thyroid gland, producing what is usually called goitre, occurs sometimes before birth, frequently during childhood, more often at the age of puberty, and occasionally in later life. It may be confined to one lobe or to some part of it, or may affect the entire gland. It may be temporary, from congestion caused by valvular heart-disease, during the period of menstruation, at the time of confinement, or it may be permanent. The permanent cases are either benign or malignant. In the benign enlargement there is an increase of tissue of one or more of the component parts of the gland, but it retains the gland-structure. In the malignant enlargement the growth of tissue does not conform to the structure of the gland. It is an adventitious tissue, usually carcinoma or sarcoma, and occurs most frequently where goitre is endemic or epidemic.

In the formation of goitres three principal varieties may be considered, namely, the follicular, the fibrous, and the vascular. In the follicular variety the first step is an increase of the cylindrical epithelia lining the vesicles. This leads to a growth of the vesicle itself which finally divides, forming two. Thus, in this variety, there is not only an increase in size of the vesicles, but also an increase in number. The vesicular goitre is soft and semi-fluctuating. Cysts are formed by the pressure of these vesicles producing absorption of the adjacent walls, thus converting many vesicles into one cyst. The fibrous form is produced by an increase of the connective tissue forming the framework of the gland, and which surrounds the vesicles. It may be increased to such an extent that the vesicles are almost entirely obliterated, and the gland feels hard and resistant.

In describing the vascular form it must be remembered that the thyroid gland is supplied by four, sometimes by five arteries: two superior thyroids from the external carotid, two inferior from the subclavian, and occasionally a middle thyroid from the innominate artery. These arteries enter the gland, divide and subdivide in the connective tissue, and finally form a network around each vesicle. The blood is returned by six veins. The two superior open into the internal jugular. The two middle make a connection with the thyroid circuit and open into the internal jugular. The two inferior open into the right and left innominate veins. In the vascular form of goitre the arteries may be especially enlarged—those on the surface as well as the branches which penetrate the gland-substance—giving it a strong pulsation which is often very noticeable on inspection. The veins are enlarged much oftener than the arteries—the so-called *struma varicosa*. The small veins in the glands become varicose, tortuous, and greatly enlarged. The veins on the surface are often enlarged into wide channels.

The cysts which are found in goitre, instead of containing the clear albuminous fluid natural to the vesicles, are often filled with a colloid substance, colorless, yellowish, or of a greenish color. It is thick and sticky, and contains "kernels" and epithelia, and, according to Virchow, is probably produced by a chemical change of the normal albuminous contents of the vesicles. The cysts may also be filled with blood, due to the rupture of a bloodvessel in the cyst-wall, generally caused by amyloid degeneration rendering the arteries inelastic and brittle.

Etiology.—Among the predisposing causes of goitre are age, and especially the period of puberty. The menstrual period and pregnancy are apt to lead to a swelling of the gland, which is at first only vascular, but which often results in an increase of connective tissue which is permanent. An increase of the circulation from nerve-irritation is also a cause, as seen in Basedow's disease. The blowing of wind-instruments, ascending mountains, lifting heavy weights, an imperfect return of the venous blood as in heart-disease (right side), may each be causative. It may be congenital. Some

countries are almost entirely free, while in others, especially in valleys lying between high mountains, as in parts of Styria, Tyrol, and Switzerland, goitre is endemic and often epidemic. In some valleys nearly every inhabitant is affected. Not only those who have always lived there, but also those who for a considerable time make their residence there. The disease often attacks whole garrisons of soldiers and schools. In these regions where goitre is so constant, idiots, mutes, and cretins form a large portion of the population. Individuals suffering from idiocy or cretinism generally have goitre.

In Styria the government has established a large hospital for cretins, which is full to overflowing, and yet only a small part of the cretins of the country are accommodated.

The cause of goitre in these countries has long and diligently been sought. The social relations, the air, the water, the telluric conditions have each and all been most persistently examined. The air influenced by the surrounding mountains and by moisture has been thought, at different times and by different observers, to have much to do with the production of goitre. The water, usually strongly impregnated with lime and magnesia, has had its adherents as a causative condition. The state of the soil, often saturated with moisture and impregnated with deposits from the overflowing mountain streams, has also had many adherents. Dr. Theodore Kocher, in 1883–84, in the Canton Berne, had the surroundings of 76,606 children between the ages of seven and sixteen years examined, with a view to determine, if possible, the cause of goitre. There was a most minute and searching examination made of the soil and water, and it was found that in regions where goitre was most frequent the soil was richest in organic material; that the inhabitants drank surface-water impregnated with organic matter and rich with microörganisms; that there were some families entirely free from goitre, and that these used water from meadow springs, nearly free from both organic matter and microörganisms. From these investigations his conclusions were that in these regions the cause of goitre was the organic matter of the drinking-water.

The actual cause of goitre in these regions is yet in doubt, but the theories advanced by Lücke, Klebs, and Bircher, that goitre is caused by a microörganism, have many followers. Thus far, however, their theories have not been substantiated.

Symptoms.—The growth of goitre is usually slow, and ordinarily produces no marked symptoms until it has attained a large size, when it may seriously impede respiration from pressure on the larynx or trachea. Lobules situated beneath the sternum, on the trachea, or between the trachea and œsophagus, are very apt to produce injurious pressure; or when one lobe or part of a lobe is considerably enlarged, harm is produced by pressure on the side of the trachea.

Where the gland is much enlarged and the sternohyoid and thyroid muscles are rigid, they press the gland down tightly and thereby cause stenosis of the trachea. It is also held that by considerable and long-continued pressure on the larynx or trachea fatty degeneration is produced, making them pliable, and that by a sudden twisting of the gland a kink in the trachea may be produced, resulting in death from asphyxia. Pressure of the gland may produce paralysis of the vagus or of the recurrent laryngeal nerves with a fatal result. Billroth states that such deaths, resulting from goitre, are much more frequent than is generally supposed. Death may be produced not only by paralysis, but also by irritation of the nerves, causing spasm of the muscles of the larynx.

Stenosis of the œsophagus with difficult deglutition may also occur when a portion of the gland has grown between the œsophagus and trachea.

Pressure on the carotids may occur, producing anæmia of the brain, and on the jugular veins, causing a stasis of blood in the head.

Treatment.—The approved methods of treatment practised at the present time may be considered under five heads:

1. The use of iodine.
2. Electrolysis.
3. The treatment of cysts.
4. Ligation of the thyroid arteries.
5. Extirpation.

The treatment of goitre by iodine, externally, usually in the form of a salve, and internally by the administration of potassium iodide, has long been practised, and often with good results, especially in cases which have not attained a large size, and are not of long duration. Its action consists chiefly in causing absorption of the connective tissue, and its external use may also produce, in the superficial parts, inflammation, matting together, and consequent shrinkage.

The parenchymatous injection of tincture of iodine is followed by much better results. This was first recommended by Lücke, in 1867. It is especially applicable in cases of goitres which are soft and which involve only a part of the gland.

In advanced age a goitre usually undergoes degeneration, becomes hard from the deposit of lime salts; or large cysts with rigid walls are formed. In these cases injections are useless. Practised with strict anatomical and antiseptic precautions injections are attended with but little danger. Still there have been cases with great difficulty of respiration, and even death following the procedure. Bruns ascribes death, in some cases, to paralysis of the

vagus. In other cases suppuration has followed, and in still others the injection has entered one of the large veins, producing thrombus.

Dr. Heymann has collected the records of sixteen deaths from parenchymatous injection, but these unfortunate results are so very rare that they may almost be disregarded. In making the injections the strictest antiseptic precautions should be observed—the syringe carefully cleansed either by heat or by carbolized solution, and the patient's neck well washed with a carbolized solution. Avoiding any large veins that may be on the surface of the gland, the needle is thrust directly into some enlarged portion, care being taken first to fix the part with the thumb and finger, then one-third or one-half of a syringeful is slowly thrown in. The injections are practised usually twice a week, but the frequency and the amount of iodine injected are governed by the degree of reaction. Generally after one or two injections an entire syringeful can be used, selecting a new point where the gland is soft. Before the injection is finished, or immediately afterward, the patient complains of severe pain in the teeth, eye, ear, or in the maxillary articulation, always on the side on which the injection has been made. If the injection has been made low down near the sternum, the patient will complain of severe pain in the chest, and there may be for a time difficult breathing. In over-sensitive girls this pain may continue for several hours. The injections produce an inflammation in the substance of the gland, matting the tissues into a hard lump which causes shrinkage at that point. Its specific alterative effect is also considerable.

Case I.—Annie H., aged eighteen years; enlargement of both lobes of thyroid, which had been noticeable for two or three years. A neck-chain that she formerly wore, would not clasp by an inch; the gland was soft. Four injections were made, two on each side, at intervals of three days. This reduced the gland to two hard nodules, and she could again wear the neck-chain.

Case II.—Annie R., aged twelve years; enlargement of both lobes of thyroid, but especially of the right. Enlargement was very marked and produced a feeling of suffocation. Eight injections were made, when the visible swelling had almost entirely disappeared and only some hard nodules could be felt.

The foregoing has been substantially the result in a large number of cases in which the injections have been used, and in no case have unpleasant results followed any of the injections. It would seem that in this part of the country, where goitre is sporadic, few if any cases would attain considerable size if timely injections were practised. Substances other than iodine have been used, such as diluted alcohol, solutions of ergotin and of arsenious acid, and iodoform emulsion, but none of them has been found to produce such uniformly good results as iodine, while the injection of some has led to the production of suppuration.

Electrolysis.—Mr. John Duncan[1] gives the results of treatment of this method in fourteen cases of goitre. Six were entirely cured, and the others more or less benefited. Weimbaum reports two cases cured by electrolysis. This method of treatment promises well, and is practised by using a galvanic current of from six to eight cells. The electrodes are needles, which are thrust into the gland and moved about in its substance. The sitting is maintained for from ten to fifteen minutes.

In long-standing goitre cysts may occur. In some cases there will be but one cyst, in other cases many. They are formed by the enlargement and coalescence of the original vesicles. As the vesicles enlarge they are closely pressed together, their adjacent walls become absorbed, and a large cyst may be formed from many small ones. In old cases the walls of these cysts are often thick, rigid, and infiltrated with lime salts.

There are three methods of treating the cysts usually recommended:

1st. Puncture and the injection of iodine.

2d. Incision.

3d. Enucleation.

Puncturing a cyst with a canula, and injecting iodine, is the simplest method, and can be practised with success in single cysts, with thin walls. Where the cyst-walls are firm, or where several are in close conjunction, incision offers better results.

Incision should be done under strict antiseptic precautions, cutting down to the cyst-wall, which is stitched to the skin before opening (Kœnig). The cyst is then incised to the full extent of the external wound, irrigated with a carbolic acid solution, and drained. If there is much bleeding from the cyst-wall the cavity should be packed with iodoform-gauze. Healing is not so certain as after the old method of leaving an open, suppurating, granulating wound, but it is far less dangerous.

In cysts with thick, rigid walls, or containing much solid matter, enucleation is to be preferred. This is performed by making an incision down to the wall, and then shelling out the cyst with the fingers, with closed scissors or with dressing-forceps. The cavity is then irrigated and drained, and an antiseptic dressing applied.

Case III.—Mrs. H., aged thirty-four years; sought relief from a cyst of the right lobe of the thyroid, near the median line. There had been a gradual enlargement for several years, which at the time of the consultation was the size of a small apple. Its walls were thin, and the cyst superficial. After thoroughly cleansing the region, a small trocar was

[1] British Medical Journal, November 3, 1888.

thrust into the cyst, its contents, a thin albuminous fluid, were allowed to drain off, and half a drachm of tincture of iodine thrown in through the canula and allowed to remain. The reaction was slight, and complete obliteration of the cyst followed.

Case IV.—Maggie H , aged twenty-four years; consulted me on account of a cyst of the thyroid, directly over the trachea. The cyst had been growing for four or five years, and was the size of a small hen's egg. The patient was anæsthetized, the parts carefully cleansed, and an incision made directly over the cyst and down to its wall, when it was easily shelled out. The pedicle containing the bloodvessels was ligated with antiseptic silk and an antiseptic dressing applied. Healing occurred by first intention.

In order to avoid the misfortunes and dangers which have sometimes attended or followed extirpations of goitre, Wölfler, during the last few years, has revived the operation of ligating the thyroid arteries. In his monograph, published in 1887, on the history of goitre operations, he gives Walther (1814) the credit of first ligating the superior thyroid arteries for the purpose of producing atrophy of the gland, and to Porta (1850) the credit of first ligating the four thyroids for the same purpose, with successful results. The number of cases to which the operation is applicable seems limited. Billroth[1] states that the operation should be performed only in cases of goitre that are well nourished. In cases in which degenerative processes or large extravasations of blood have taken place, in which the goitre is largely cystic with thick, firm walls, or in which there is a deposit of lime salts in the tissues, the operation is contra-indicated. The operation is applicable to much the same class of cases as are the parenchymatous injections. Performed under strict antiseptic precautions the operation should be practically free from danger, though often difficult, and in well-selected cases it seems probable that it may take the place of the more radical and dangerous operation of extirpation.

The superior thyroid arteries are the first branches given off from the external carotids. In tying them, an incision two inches long is made at the anterior border of the sterno-cleido-mastoid muscle, with the middle of the incision over the space between the thyroid cartilage and hyoid bone. The integument, superficial fascia, and platysma myoides are divided, the deep fascia torn through with dissecting-forceps, or divided on a grooved director. When the operator reaches the artery, it should be ligated in two places with imbedded aseptic silk sutures.

In tying the inferior thyroid Billroth recommends an incision at the posterior border of the sterno-mastoid muscle, the incision terminating an inch above the superior border of the clavicle. The skin and platysma are cut through, tying any veins, with two ligatures, that may be in the line of the incision, before cutting them. When the deep fascia is incised one comes directly upon the scalenus anticus muscle with the phrenic nerve coursing down its centre. This is the deep landmark of the region. Then, by raising the border of the sterno-mastoid muscle and separating the connective tissue, the inferior thyroid artery is reached.

In this incision the operator does not see the origin of the artery, and in order to be sure that the vessel is the one desired it should be traced upward, when it will be seen to curve under the common carotid artery. For greater security the artery should be ligated in two places and incised.

Case V.—Mrs. D., aged twenty-seven years. At the age of nineteen she first noticed a slight fulness and pulsation in the neck. The increase in size was gradual until she became pregnant, four years after first noticing the enlargement. During this and a subsequent pregnancy the increase was rapid; there was much difficulty in respiration, which was noticeable at all times, especially at night, when it was necessary for her to be propped up in bed. She was also almost constantly troubled with a hoarse, croupy cough. The gland pulsated strongly in every part. Her neck measured above the gland 34 centimetres, and over the greatest enlargement 48 centimetres.

August 22, 1889. The four thyroid arteries, excepting the right inferior thyroid, were tied at one sitting in the usual manner. In the region of the right inferior thyroid the gland extended so far beneath and beyond the external border of the sterno-mastoid muscle that it was feared great difficulty might be experienced in reaching the artery; consequently an incision was made one inch above and parallel with the clavicle, incising integument, platysma, and deep fascia. The anterior border of the sterno-mastoid being forcibly raised with the index-finger and the deep connective tissue torn open, I easily came upon the first portion of the subclavian artery, doubly ligating and dividing the middle thyroid vein which crossed the deep part of the wound. The thyroid artery was then exposed and doubly ligated. The artery was very large—the size of a large goose-quill. All pulsation in the gland had now ceased; it felt like a sponge saturated with water and could be easily emptied. The wounds were irrigated with bichloride solution, drained and united with a continuous silk suture. A very heavy antiseptic dressing was applied, extending well down on the chest, the bandage encasing not only the neck, but the head and chest as well, in order that the muscles of the neck would be at rest. The dressing was changed on the seventh day, the tubes and sutures removed, and complete union found. The cough and difficult breathing were completely relieved, and thus far there has been no return. The gland decreased to about one-half of its original size, when it remained stationary.

Extirpation.—Perhaps no operation in surgery has had a more varied experience than extirpation

[1] Wiener klinische Wochenschrift, No. 1, 1887.

of the thyroid—at times recommended by some of the best surgeons and strenuously opposed by others equally good.

In 1791 Desault made the first successful extirpation of one-half of a goitre, and in 1800 Hedenus made two total extirpations, both successful (Wölfler). Still, the operation was, perhaps, justly condemned, and it was not practised to any extent until the advent of antiseptic surgery. In 1875 Küster made the first extirpation with strict antiseptic methods.

In 1877 both Albert and Billroth extirpated goitre under antiseptic precautions. From this time the operation became more popular. The favor with which it was now held was not entirely due to the antiseptic precautions, but perhaps quite as much to a better technique.

As illustrating the disfavor in which the operation was formerly held I quote the following from Gross's *Surgery*:[1]

"But no sensible man will, on slight considerations, attempt to extirpate a goitrous thyroid gland. If a surgeon should be so adventurous or foolhardy as to undertake the enterprise I shall not envy him his feelings while engaged in the performance of it, or after he has completed it, should he be so fortunate as to do this. Every step he takes will be environed with difficulties, every stroke of his knife will, if he is not perfectly self-possessed and most cautious, be followed by a torrent of blood, and lucky will it be for him if his victim live long enough to enable him to finish his dissection."

This would perhaps be as true now as then, were it not for better methods of operating. There were formerly two great dangers attending extirpation, namely, hæmorrhage and suppuration. These two sources of danger are now happily almost wholly under control.

In the experience of surgeons who have had most to do with this operation other difficulties also have followed, namely, tetany and cachexia strumipriva. If tetany occurs it is usually on the day following the operation. There are at first pains in the extremities, which are soon followed by muscular spasms in the legs. The upper extremities are also soon affected, as well as the muscles of the face. These tonic muscular contractions may be of short duration, the patient quickly recovering, or they may continue for an indefinite period, reducing the patient very much or even leading to death. In Billroth's first seventy cases of extirpation, tetany occurred seven times (Wölfler). The cause of tetany in these cases is not well understood, but it is thought to have some connection with impoverished blood, and perhaps it is excited by irritation of the recurrent laryngeal nerve. Dr. James Stewart[2] affirms that tetany never occurs unless the entire gland has been removed.

[1] Edition of 1872, page 431.

[2] American Journal of the Medical Sciences, November, 1889.

What is of far more serious import is cachexia strumipriva. This condition has been especially observed in Switzerland (Reverdin and Kocher). It generally occurs during the first month after the operation. There is general disturbance of nutrition, loss of flesh, and muscular weakness. The mind is benumbed, the lips and tongue and eyelids swollen, and difficulty of speaking occurs. This condition is one of cretinism and is lasting, but occurs only when the entire gland has been removed, and more especially in young persons. So uniformly has this been the case, that it has become a rule never to extirpate the entire gland before puberty. If even a small portion of the gland is left the cachexia does not occur. In persons past the age of puberty the condition is not apt to occur even after complete extirpation.

Schiff has advanced the opinion that the thyroid gland has a regulating function on the circulation in the brain, and that after complete removal the marasmus is produced by chronic anæmia of the brain.

The most approved method of operating at the present time is that of Kocher and Billroth. According to Wölfler, these two surgeons have removed more goitres than any other two men in the world. An incision is made in the median line, from near the sternum to the hyoid bone, and if necessary it may be extended on either side, or on both sides, in the form of the letter Y, to the sterno-cleido-mastoid muscles. The anterior jugular vein, and perhaps the external jugular, may be under the line of the incision; if so, they should be doubly ligated and incised. In separating the tissues it will be found necessary to touch the sterno-hyoid and omo-hyoid muscles if the gland is large. When the capsule of the gland has been reached the knife should be laid aside and all tissue doubly ligated *en masse* before being cut. The dissection is made with dissecting-forceps and with the fingers, the gland being shelled out first at the superior border of one side. Reaching the superior thyroid vessels, artery and vein, they are doubly ligated and incised; the dissection is carried down the same side until the inferior thyroid vessels are reached, which are also doubly ligated and cut. The greatest care should be exercised in this region not to injure the recurrent laryngeal nerve. The dissection is now carried below, tying the middle thyroid vein and artery, if the latter exists, separating the gland from the trachea, and ligating any vessels that may be found. The goitre is then lifted from its bed and the vessels on the opposite side ligated. The wound is irrigated and drained, united with a continuous silk suture, and a large antiseptic dressing applied.

In this operation one of the most important considerations is the prevention of hæmorrhage, and

the advice of Billroth on this subject should never be forgotten; namely, that when the capsule of the gland has been reached, lay the knife aside and doubly ligate all tissues before cutting them.

Case VI.—G. D., aged twenty-four years, first noticed the neck enlarging five years ago. Numerous attempts were made to check the growth by the external application of iodine, but with no effect. The increase in size was continuous. In August, 1889, both lobes were found very much enlarged. Some difficulty in respiration was experienced and great inconvenience felt on account of the increased size of the neck in wearing a collar. The gland felt firm and hard to the touch. August 13th, extirpation was performed. Great difficulty was experienced in separating the overlying tissues from the gland, as they were matted together in consequence of the iodine applications; and in making the separation a cyst the size of a large crab-apple was broken into. After the gland was freed from the overlying tissues, little difficulty was experienced in shelling it out. The vessels were ligated as they appeared, the wound was irrigated, drained, and united with a continuous silk suture, and a heavy antiseptic dressing was applied. On the eighth day the dressings were changed and the wound found united throughout. Patient has remained perfectly well up to date.

AN ANALYSIS OF THE OCULAR SYMPTOMS FOUND IN THE THIRD STAGE OF GENERAL PARALYSIS OF THE INSANE.[1]

By CHARLES A. OLIVER, M.D.,
of Philadelphia.

These observations and their deductions, which form a part of, and in fact conclude those which were presented to the American Ophthalmological Society at its last annual meeting, are here given in hope of offering a few more facts to the ocular symptomatology of general paralysis.

Care was taken that each subject was seemingly free from any gross extraneous disease or local disorder, and discretion was exercised that competent and authoritative medical opinion had been given as to the type and stage of the general complaint; also, for reasons given in the previous paper, the study has been limited to the male sex.

In a disease of such complex symptomatology, where doubtless quite a number of pathological peculiarities exist at one time, accurate pathognomonic changes cannot be expected in each case, and for this reason a great number of seemingly similar cases have been studied in the effort to obtain an idiocratic picture of a few of the oculo-motor and retinal changes to be found in this disorder. However, as the disease seems, as shown by the microscope, to expend its greatest force upon both the motor and sensory regions of the cerebral cortex, with involvement of the related higher mental areas, the symptoms which are improperly described as paretic only, assume types of both motor and sensory derangement, with associated mental peculiarities of a distinctive character. As a part of these, the ocular apparatus, with its six channels on each side to the cortex of the brain, becomes not only a useful situation from which to study these changes, but is really invaluable as an exponent of the intracranial changes.

Observations.[1]—1. Direct vision for form was reduced in every instance where obtainable to any degree of certainty.

2. Direct vision for color was subnormal in the few instances in which it could be properly studied, showing itself more particularly for green and red.

3. Accommodative action: though impossible to obtain any reliable results by various subjective methods, yet by objective means (retinoscopy) this was seemingly lessened in every unequivocal case tried.[2]

4 Visual fields: no determinate answers could be obtained.

5. Pupils, as a rule, were somewhat larger than normal.

6. Pupils were ofttimes unequal in size, and, in some instances, had a difference of one or two millimetres in their longer diameters.

7. Pupils were frequently oval and ovoid in shape; their long axes being opposed to one another or placed at equivalent angles.[3]

8. The pupillary border of the iris in several instances was quite irregular in outline, without any evidences of localized inflammatory change.

9. Changeability of pupillary form still persistent in one case in which it had been so noted in the second stage of the disease.

10. Irides were devoid of any gross peculiarities in comparative tint.

11. Irides, as a rule, were either extremely slow in response or absolutely immobile to the strongest light-stimulus, though fairly responsive to efforts for convergence and accommodation.

12. The iris of the larger pupil, in some instances, was not so responsive to light-stimulus as its fellow, this inequality of action seeming to bear no relation to the degree and character of refraction-error, and, in some cases, seemingly free from the apparent amount of optic-nerve change.

[1] Paper read before the American Ophthalmological Society, July 17, 1890.

[1] A portion of these observations will form a part of the Fifth Annual Report of the Ophthalmological Department of the State Hospital for the Insane at Norristown, Pa.

[2] Curiously, one case upon several occasions gave distinct ophthalmoscopic evidence of spasm of accommodation.

[3] It must not be forgotten that the pupils of many of the mentally healthy present similar characteristics, especially in cases of astigmatism, where asthenopia is complained of.

13. The secondary movements of the iris were almost, if not entirely, lost in all instances in which light-stimulus produced a reflex act.

14. Irides, in quite a number of cases, were very feebly responsive to efforts for accommodation and convergence only; the want of this character of action being very changeable and unequal at the same time upon the two sides.

15. Irregular and incomplete dilatation of the pupil followed the employment of strong solutions of atropine—sufficient to give full mydriasis in ordinary subjects—the comparative positions of the greatest amounts of pupillary enlargements being unequally situated at fifteen and thirty degrees differences, although several cases yielded peculiar and fantastic forms.

16. Insufficiency of the interni was noted in several cases, though on account of the mental condition of the subject nothing could be positively determined.

17. Ataxic nystagmic motions of the extra-ocular muscles were present at times in a few cases, especially noticeable with the third and sixth nerve distributions, either in separated or conjoined action.

18. The optic disks, in many instances, were decidedly and unequally semi-atrophic, the degeneration being especially pronounced in the deepest layers and on the temporal side of the nerve.

19. The capillarity of nerve-substance was materially lessened, the greatest amount of blood-supply being recognized in a rather narrow crescentic area on the nasal side of the disk.

20. The disk, in a few cases, was of a suffused and gelatinous appearance, its edges being plainly seen, and the surrounding retina somewhat œdematous.

21. A series of minute venous and arterial loops in the retinal vessels on the disk were seen in one well-marked case.[1]

22. The scleral ring was sharply cut all around and quite broad; this, as a rule, being more noticeable on the temporal side of the disk.

23. Blackish crescents of pigment, broken and somewhat absorbed beyond the scleral ring, at the outer edge of the optic-nerve head, were frequent.

24. Pigment-lines of different widths and varying degrees of absorption were seen beyond the scleral ring at the inner edge of the optic-nerve head.

25. The pigment-layer of the retina was, as a rule, diminished in thickness, the greater amount of striation being seen at the superior and inferior borders of the optic disk.

26. Retinal striation, in a few instances, was very pronounced, rendering the disk-edges quite hazy.

27. Retinal arteries were reduced in size and sometimes slightly tortuous.

[1] Acquired syphilis was suspected in this case.

28. Retinal veins were somewhat undersized and quite tortuous in a number of cases.

29. Blood-currents of the retinal vessels were apparently normal in tint.

30. Very few lymph-reflexes were seen, these being generally situated in the walls of the main retinal stems.

31. Fine pin-point opacities in the retina between the disk and the macula were seen in two cases; no other gross changes in the retina.

32. The choroid was granular and disturbed in the majority of cases.

33. Refraction was generally hypermetropic, with a marked degree of astigmatism.[1]

Summary and Conclusions.—1. The oculo-motor symptoms of the third stage of general paralysis of the insane, which consist in varying, though marked degrees of loss and enfeeblement of iris-response to light-stimulus, accommodative effort and converging power; lessening of ciliary muscle tone and action; weakening and inefficiency of extra-ocular muscle motion—all show paretic and paralytic disturbances connected with the oculo-motor apparatus itself, of greater amount and more serious consequence than those seen in the same apparatus during the second stage of the disease.

2. The sensory changes of the third stage of general paralysis of the insane, which, though similar to those found in the second stage of the disorder, are so pronounced as to show a semi-atrophic condition of the optic-nerve head and marked reduction in the amount of both optic-nerve and retinal circulation, with consequent lowering of centric and excentric vision for both form and color—all indicate a degenerate condition of the sensory portion of the ocular apparatus, with impairment of sensory nerve action.

3. The peculiar local changes seen in these cases, which consist in conditions of the choroid and retina indicative of local disturbance and irritation of these tunics, more pronounced than those seen during the second stage of the disease—all represent the results of greater wear and tear given to a more delicate and a more weakened organ.

4. Both the motor symptoms and the sensory changes of the ocular apparatus, as thus described in the advanced or third stage of general paralysis of the insane, furnish not only evidences of a local disturbance of a more pronounced type than those shown in the second stage of the disorder, but plainly show themselves as one of the many peripheral expressions of fast-approaching degeneration and dissolution of nerve-elements most probably connected with related cortex-disintegration and death.

[1] Thanks are due to Drs. Henry Sidebottom and Henry C. Cattell for their kind assistance during the study of these cases.

CLINICAL MEMORANDA.

SURGICAL.

Abscess of the Liver. Operation: Recovery.—T. R., aged twenty-seven years, laborer, entered the Philadelphia Hospital, August 16, 1889, suffering from fever and severe pain in the side. He stated that he had always enjoyed good health, with the exception of an attack of jaundice from which he suffered for six weeks when in his sixteenth year. During May last, while much exposed, he contracted dysentery. This became severe in type and confined him to his bed for two weeks. He resumed work before recovery was complete, suffering from occasional bloody stools for nearly two months. About the first of August he experienced considerable pain over the right iliac crest. The bowels were at this time costive. Shortly afterward he noticed a tumor in the region of the liver. At no time were there chilly sensations. His symptoms steadily grew more pronounced until he entered the hospital.

On admission the temperature was 103°, the pulse 100, the respiration 30. The liver-dulness extended three inches below the ribs in the liver-line, forming a distinct tumor visible on inspection and tender on palpation, but showing no signs of fluctuation or superficial œdema. Auscultation failed to detect friction-sounds. Rectal examination showed the absence of any accessible ulcerating foci. The following day the temperature reached 104°, and the general condition of the patient had markedly altered for the worse. An operation for the evacuation of pus was at once performed. An incision three inches in length was made over the most prominent part of the tumor. The abdominal muscles were divided to the full extent of the wound down to the peritoneum, and the cavity of the latter was opened just below the tumor. The tumor at its most prominent part was found to be firmly adherent to the peritoneum. The opening into the general cavity was protected by a sponge and the point of the knife was thrust through the adhesions into a liver-abscess the size of a large orange. By means of the finger passed into this cavity, the walls of two other abscesses were broken through and about a pint of thick, bile-stained pus was evacuated. Two large drainage-tubes were carried to the deepest parts of the suppurating cavities, the wound was washed out with sterile normal saline solution (0.7 per cent. sodium chloride) and the wound was closed. The patient was under ether for thirty minutes. On the following day the temperature dropped to normal, and the subsequent course of the case was one of uninterrupted recovery, with the exception of a small stitch-abscess which developed on the fifth day and sent the temperature up to 101°. In two weeks the drainage-tubes were removed, the discharge having entirely ceased, and in three weeks the patient was sitting up. His subsequent history shows that he has enjoyed robust health and has never suffered from any trace of his liver trouble.

It is interesting to note in this case that, although the suppurative trouble was immediately due to septic emboli carried from ulcers of the lower bowel; the operation was successful in evacuating all abscess-cavities of the liver. A study of many autopsies shows that such abscesses are generally multiple, the liver frequently being completely riddled and destroyed. Indeed this is so frequently the picture that many pathologists advise against operation in these cases, maintaining that the trouble is so disseminated as to be beyond the help of the surgeon's knife. Though the abscesses were multiple in the case reported, they were separated from each other by such thin walls that the latter were readily broken down. Even had this latter procedure not been deemed advisable, it is more than probable that in one or two days at the most these remaining collections of pus would have ruptured in the direction of least resistance, thus spontaneously evacuating their contents.

A month after operation a blood-count was made to see whether such extensive destruction of liver-tissue had any effect upon the number of corpuscles. The latter seemed normal in color, and as a result of repeated observation gave an average number of 4,000,000 to the c.mm., a percentage not lower than could be reasonably expected after a month's stay in a crowded hospital-ward.

Edward Martin, M.D.,
Assistant Surgeon to the
Hospital of the University of Pennsylvania

RHINOLOGICAL.

Anosmia from Tobacco-poisoning.—Tobacco-amblyopia is now a well-recognized disease, and is daily becoming a more familiar example, and an alarming evidence, of the growing abuse of tobacco-smoking.

A recent case leads us to believe that the nerve of smell as well as, though less frequently than, the nerve of sight, is sometimes injured by excessive smoking. Reference has been made to many of the standard works on the subject of anosmia, and various are the causes which are said to produce it. In the order of their frequency syphilis, traumatism, catarrh, obstruction of the nares, strong fumes, and malaria are enumerated, but we are unable to find that tobacco is held responsible for the loss of smell. This fact leads us to bring to the attention of the profession what we believe to be a case of tobacco-anosmia.

In March, 1890, Mr. A. S. F. applied for treatment, and stated that about a year ago he began to suffer from dryness of the post-nasal region and a disposition to clear his throat. Then he noticed a feeling of fulness or stuffing in his nose and a slight difficulty in nasal respiration, sometimes in one nostril, and, again, in the other. Lately he had observed that he had lost the sense of smell.

There was no specific history. He was, however, an inveterate smoker, and was in the habit of blowing the smoke through his nostrils.

Examination showed pharyngitis and an atrophic rhinitis. His sight was also slightly impaired, and this led us to suppose that tobacco was the cause of the condition.

This diagnosis subsequently proved correct, as was conclusively proven by the cure of the disease by removing the cause.

The treatment consisted mainly in total abstinence from tobacco-smoking, the administration of one-thirtieth grain of strychnine three times a day, and in the application of electricity to the nasal mucous membrane by means of a pledget of wet cotton on the end of an elec-

trode. In about a month the power of smell began to improve, and when last seen and tested he could recognize almost any moderately strong odor.

The effect of tobacco on the eye is known to be an atrophic condition of the optic nerve resulting in amblyopia; hence it is an organic disease.

Now the sense of smell, though primarily dependent on the olfactory nerve, is secondarily dependent on several conditions, the most important of which are moisture and an unobstructed nasal passage.

Hence, anosmia may be either organic or functional, and tobacco-poisoning is, in our opinion, capable of producing either, or both. The anosmia is functional, when we have an interference with the secondary conditions necessary for the sense of smell; organic, when we have the nerve sensibility destroyed by atrophic changes.

From personal experience and from actual observation and inquiry, we are convinced that smoking is especially injurious to the nasal and post-nasal fossæ, and that by it the sense of smell is apt to be impaired, and may be destroyed.

Edward F. Parker, M.D.

Charleston, S. C.

MEDICAL PROGRESS.

Aristol in the Treatment of Skin Diseases.—In a letter to the *Journal of Cutaneous and Genito-urinary Diseases*, September, 1890, Dr. L. Brocq, of Paris, communicates some of his results with aristol in the treatment of cutaneous diseases. In his experience the drug acts only as a cicatrizant. In chancroid its use does not seem to exert a favorable influence on the virulence of the disease. In tertiary syphilitic ulcerations it apparently hastens cicatrization, provided that appropriate general treatment with mercury and potassium iodide is also used. Cicatrization in tuberculous diseases of the skin is also hastened by applications of aristol. Applied to non-ulcerated lupus vulgaris or erythematous lupus, it exercises no useful influence. In tuberculous ulcerations of mucous membranes it is useful, and by means of it Dr. Brocq was able to secure cicatrization of an extensive tuberculous ulcer of the arch of the palate. In superficial epithelioma aristol does not seem to exert any destructive influence on the pathological cells; but, if the growth has been destroyed by caustics, by curetting, or by the hot iron, the drug hastens cicatrization. The author's method of treating this disease is to curette the base thoroughly, and if he believes that the diseased tissue is completely removed, to dress with aristol. If the disease is apparently not completely removed, he applies potassium chlorate, either in powder or solution, for a few days, and then uses aristol.

In the treatment of psoriasis, aristol has given the author scarcely appreciable results. To test its value thoroughly in this disease, he has treated all his cases with aristol on one side of the body, and with the ordinary applications on the other.

In no instance has Dr. Brocq seen aristol produce toxic symptoms.

Incision and Drainage in the Treatment of Hydrocephalus.—Pott (*Der Kinder-Arzt*, August, 1890) reports the case of a child, four weeks old, with marked hydrocephalus, in which he punctured the skull and drew off ten ounces of fluid. The psychical symptoms immediately improved, though for only a short time, and in twenty-four hours the fluid had re-accumulated, distending the skull to its former size. The author then made an incision through the lower third of the right fronto-parietal suture, inserted a drainage-tube, and applied a compressing bandage to the head. The child at first improved, but died on the twelfth day after the operation. At the autopsy both lateral ventricles were found full of fluid, and, as there was no communication between them, the evacuation of one had not reduced the fluid in the other.

Methods of Disinfecting the Hands.—Geppert (*Centralblatt für die medicinische Wissenschaften*, July 26, 1890) advises the following method of disinfecting the hands previous to operating: Cover the hands with a paste made by mixing 100 parts of powdered chloride of lime with 45 parts of water. Then dip them for a few moments in a three-per-cent. watery solution of hydrochloric acid. Or, in place of this, the hands may be alternately dipped into a chloride of lime solution and three-per-cent. hydrochloric acid solution.

Mikulicz (*Der Frauenärzt*, August, 1890) disinfects his hands by first cleaning the nails, then scrubbing the hands for three minutes with potash soap and water, soaking them for half a minute in a three-per-cent. carbolic acid solution, and finally washing them off with a 1-to-200 sublimate solution.

Prognosis in Extravasation of Urine.—According to Dr. J. Blake White (*Journal of Cutaneous and Genito-urinary Diseases*, September, 1890), the prognosis of operations in cases of urinary extravasation can be estimated as follows:

1. Should the infiltration not have extended beyond the perineal structures before operation, the prospects of recovery are favorable.

2. Should the infiltration have involved the scrotum and the perineal structures, the operation, though affording the best chances of recovery, is not without hazard.

3. Should the infiltration extend into the perineum and scrotum, and involve also the ileo-abdominal region, the danger to the patient is greatly increased.

4. Should the infiltration descend to the ischio-rectal space, the prospects are exceedingly gloomy, since it threatens deep-seated sloughing, and, in consequence, profound shock.

Large Doses of Potassium Iodide in Tertiary Syphilis.—Wolf (*Revue de Thérapeutique*) administers potassium iodide in doses of from 450 to 750 grains daily to obstinate cases of tertiary syphilis. The drug is dissolved in a decoction of rice in order to prevent iodism, any free iodine formed in the stomach being immediately converted into iodide of starch.—*London Medical Recorder*, August, 1890.

The Diazo-reaction in Diagnosis.—Dr. L. Rütimeyer, who has made between two and three thousand trials of the so-called diazo-reaction in the urine from 260 patients,

believes that it is a very useful guide, both in diagnosis and prognosis, being especially valuable in phthisis and typhoid fever. In phthisis he regards it as denoting the absorption of caseous matter, and, when it is persistent, as implying rapid mischief and an early and fatal termination. In cases of general miliary tuberculosis it was always obtained. A large number of typhoid cases were examined and the presence of the reaction was very constant, and could generally be obtained early. It does not seem to be present in pyrexial intestinal catarrh.

In the diagnosis of typhoid fever, if the reaction is not obtained during the first or second week, the case, if typhoid at all, must be a very slight one. It cannot, however, be affirmed that a well-marked and constant diazo-reaction is a sign of a fatal termination, as with phthisis.

The reaction is never given by the urine of healthy persons, and was not observed in hysteria, hepatitis, diabetes, cystitis, pyelo-nephritis, gastro-abdominal catarrh with fever, or in a number of surgical diseases. It was occasionally present in cancer of the stomach and œsophagus, chronic nephritis, caries of bone, pyæmia, scarlatina, pleurisy with serous effusion, tubercular meningitis, and heart disease. It was more frequently obtained in croupous pneumonia.

The method of testing is very simple, two special solutions only being required, namely, a concentrated solution of sulphanilic acid in water, and a solution of nitrite of sodium of the strength of 1 to 200. The actual test-solution is prepared immediately before use, by mixing 200 parts of the sulphanilic acid solution with 10 of pure hydrochloric acid and 6 of the nitrite of sodium solution. This mixture is added to an equal volume of the urine, and sufficient ammonia added to render the whole alkaline. A bright or carmine-red coloration denotes the diazo-reaction. After from twelve to thirty-six hours a deposit occurs, the upper part of which is green or black.—*Lancet*, August 23, 1890.

Local Anæsthesia by Means of Carbonic Acid.—According to Voituriez, the anæsthetic effects of carbonic acid, described by Brown-Séquard, can be obtained in an extremely simple manner by means of the ordinary siphons containing mineral water charged with the gas. The anæsthesia is secured by projecting from a distance the contents of two or three siphons of seltzer water, limiting the application to the part to be operated upon. The insensibility to pain lasts about five minutes and then slowly disappears. The method is chiefly applicable to the limbs, as about the head and trunk the irrigation is somewhat inconvenient.—*London Medical Recorder*, August, 1890.

Gargle for Tonsillitis.—The following prescription for the treatment of tonsillitis is quoted by the *Canada Medical Record*:

R.—Ammoniated tinct. of guaiac Compound tinct. of cinchona	of each	4 drachms.
Potassium chlorate	2	"
Honey	4	"
Powdered acacia	q. s.	
Water	sufficient to make	4 ounces.—M.

Use from one-half to one teaspoonful as a gargle every two hours.

Mixture for Irritable Bladder.—Dr. W. P. Chunn uses the following mixture in the treatment of vesical irritation when due to excess of phosphates in the urine:

R.—Benzoic acid	2 drachms.
Borax	3 "
Water	12 ounces.—M.

Dose: One teaspoonful three times daily.—*Canada Medical Record.*

Eczema.—According to *L'Union Médicale*, Lustgarten recommends the following application for eczema:

R.—Oleate of cocaine	10 to 15 grains.
Lanoline	3 drachms.
Olive oil	½ drachm.

This is to be made into an ointment, and will be found particularly useful in eczema of the anus and genital organs. Two applications a day are to be made, and followed by dusting the parts with dry absorbent powders. If there is much secretion, with the formation of scabs, warm baths may be used and the foreign materials removed by either mild or strong soaps, as the case may require. In cases of pruritus of the anus, Lustgarten recommends suppositories of the oleate of cocaine.

Formula for Pulmonary Phthisis.—Gilbert recommends the following:

R.—Creasote	30 to 45 minims.
Arseniate of sodium	½ grain.
Quinine wine	1 pint.

Two small wineglassfuls should be taken directly after each meal.

Treatment of Herpes of the Genitals.—Feulard, in *L'Union Médicale*, states that where the eruption of herpes of the genitals is widespread but not severe, lotions with pure water, vinegar and water, or aromatic wine are useful, and that the small ulcers may be covered with powdered bismuth, talc, or starch. If the ulcers be severe, he recommends that they be touched with a feeble solution of nitrate of silver of the strength of from 4 to 10 grains to each 6 drachms of water; or, in place of this, the same quantity of the silver salt in the same amount of vaseline. In those cases in which there is a tendency to recurrence, it is necessary to place about the glands or under the prepuce a small piece of absorbent cotton, or similar substance, laden with tonic astringent applications.

Where the herpes is idiopathic and depends upon digestive disturbance, he recommends the use of an emetic, the employment of non-exciting foods, abstinence from alcohol, and the use of alkaline waters.

The Analgesic Action of Methylene-blue.—According to Ehrlich and Leppmann, in painful effections of the nerve-trunks methylene-blue possesses marked analgesic properties. The action is usually manifested about two hours after the administration of the remedy, and, if given in sufficient amounts, increases in intensity until the analgesia is absolute. The dose required to produce complete anæsthesia is 1 grain hypodermically or 2 to 4

grains if given by the mouth. In some cases as much as 15 grains in gelatin capsules was given daily without causing any toxic symptoms or disagreeable effects. For hypodermic administration they employed a two-per-cent. solution, which occasioned no pain and no local reaction other than a slight tumefaction which disappeared within a few days.

The authors have not discovered that the drug has any effect upon inflammatory swellings, nor were its effects very evident in the osteocopic pains of syphilis or the pain of gastric ulcer.— *Therapeutic Gazette*, August, 1890.

Hypnotism as a Therapeutic Agent.—At the recent meeting of the British Medical Association at Birmingham, papers upon hypnotism were read by Dr. Norman Kerr and Dr. G. C. Kingsbury, which excited an interesting discussion.

Dr. Kerr said that he accepted practically all the alleged hypnotic phenomena as facts, but that in hypnosis he could see only a disordered cerebral state with exaltation of receptivity. In order to decide whether hypnotism is a desirable remedy, he said that certain facts should be taken into consideration, namely:

1. That only a certain number of persons can be hypnotized.

2. That the after-effects are a disturbance of mental balance and nerve-exhaustion, and that frequent repetition tends to cause intellectual decadence and moral perversion.

3. That hypnosis is a departure from health, a true neurosis embracing the lethargic, cataleptic, and somnambulistic states.

4. That, although suffering may be assuaged by hypnosis, the underlying disease is not necessarily cured.

5. The dangers of hypnotism are great; each *séance* may bring the patient more under the control of the hypnotist, and may result in the complete submission of the former to the will of the latter.

The greatest success of hypnotism is said to be in the treatment of nervous diseases, but these are the very ailments that Dr. Kerr has seen intensified. In inebriety or narcomania no physician of repute has found hypnotism of any value.

He strongly deprecated public mesmerism as degrading, and hoped that Great Britain would follow the example of Holland and Switzerland, and prohibit such entertainments.

Dr. Kingsbury differed from Dr. Kerr in many respects. He denied that only a few people were susceptible. He thought that the unfortunate association of hypnotism with charlatanism should not prejudice us against it or prevent us from giving it a fair trial.

Dr. Hack Tuke thought that, up to the present time, the field of hypnotism in therapeutics has been very limited, but that there are sufficient grounds to warrant a further and unprejudiced trial.

Dr. C. L. Tuckey believed that hypnotism, if skilfully practised, is absolutely harmless, and, in support of that opinion, gave his own experience with 500 cases.— *British Medical Journal*, August 23, 1890.

Indications for the Use of Glycerin Enemata.—The observation of the effects of glycerin enemata and suppositories in a large number of cases has led Dr. Colubinski (*Deutsche medizinal Zeitung*) to the following conclusions:

Glycerin irritates the mucous membrane of the rectum, as shown by the burning sensation produced and by a local rise in temperature. The increased temperature and the desire to defecate are of short duration, and the latter can often be voluntarily overcome by the patient.

The irritation of the mucous membrane does not excite secretion, since the fæces evacuated after a glycerin enema are covered with glycerin only. The best results are obtained when the rectum and sigmoid flexure are filled with scybala; if fæces are in the upper part of the intestine only, glycerin is useless. According to the author, then, the cases in which glycerin enemata and suppositories are indicated are:

1. Those in which the fæcal masses are already in the rectum.

2. Cases in which the fæces are immediately above the rectum—a frequent condition in the lying-in period.

3. Those in which there is mechanical obstruction of the rectum or sigmoid, as by pelvic new-formations, pregnancy, etc.

4. Scrofulous children.

5. Persons in whom, although they have a daily evacuation from the bowels, the act of defecation is accompanied with difficulty and pain, and in whom the fæces are excessively compact.— *Therapeutic Gazette*, August, 1890.

Antifebrin and Camphor in the Treatment of Pneumonia.—Dr. Sheshmiutzeff (*Novosti Terapii*) writes that he has had excellent results in the treatment of pneumonia by the administration of antifebrin combined with camphor. To an adult he gives about five grains of the former and two and one-half grains of the latter every four hours.

According to this author, the camphor prevents the depressing effects of the antifebrin, and the temperature falls without rigors or collapse—*St. Louis Medical and Surgical Journal*, September, 1890.

The Treatment of Gonorrhœal Rheumatism.—According to the *Wiener klinische Wochenschrift*, August 28, 1890, Rubenstein has found potassium iodide a rapidly-effective remedy in the treatment of gonorrhœal rheumatism. He gives small doses, usually ordering one drachm of the iodide in five ounces of water, of which he directs the patient to take one or two tablespoonfuls in the morning, and four or five tablespoonfuls in the afternoon. In some cases he gives a still weaker solution, the patient taking one tablespoonful every hour. After a very few hours, in most cases, the pain is markedly lessened, swelling subsides, and a cure is brought about in two or three days.

As to local treatment, the author usually envelops the joint in cloths saturated with a one-per-cent. carbolic acid solution. In some cases he uses a dressing of blue ointment, in others cold, moist cloths, and in still others a solution of common salt. When the pain has disappeared he applies an elastic bandage, and if there is effusion he aspirates. Rubenstein has treated in this manner fifteen cases, some of which were acute, others chronic, and all were cured

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

THE PART PLAYED BY DOMESTIC ANIMALS IN THE TRANSMISSION OF DISEASE.

FROM time to time the daily papers or medical journals contain some small note detailing an instance where a contagious malady has been conveyed from place to place by means of pet cats and dogs, or, equally commonly, instances are given in which some domestic animal has itself suffered from a contagious disease capable of afflicting man, and so caused an isolated case or an epidemic. One of the most prominent instances where such transmission occurred was that known as the Hendon outbreak in England, in which it was supposed by some that the milk of a herd of cows affected by a disease resembling scarlet fever produced an epidemic among the children who took the milk. It has also been asserted that the fur of cats and the hair of dogs are ready carriers of contagium, and it is not at all unlikely that the cat may itself suffer from diphtheria, and that many instances of untraceable exposure to disease may have their explanation in these facts. Our attention has been called very forcibly to this subject by the report of several cases of diphtheria, due to the presence of this disease in a pigeon, by BILLIAUT in the *Journal de Médecine de Paris* of July 13, 1890. A man who was very fond of keeping these birds noticed that one of them was ill and showed evidences of severe sickness, which he could not explain, although it was evident that the respiratory passages were involved. The pigeon died, and the veterinary surgeon found post-mortem that the creature had succumbed to diphtheria. From this case the father, daughter, and a child were infected, and all suffered from diphtheria of the fauces and tonsils, with swelling of these glands and all the evidences of a typical attack of the disease. The possibility of the development of diseases in animals which generally affect the human being, is overlooked chiefly because very few of these diseases are supposed to be capable of existence in blood possessing so high a temperature as that of most of the domestic animals, and particularly that of the pigeon, whose normal temperature is so very high. That a cat in its daily wanderings may play in the room of a sick child and then return to that of a well child is so possible that it is curious we do not see more instances in which such an accident occurs. Perhaps contagion is frequently so carried, though we fail to recognize the fact.

THE VALUE OF SALOL.

WHEN a new drug comes before the profession for trial it goes through two stages of existence, in the first of which it is generally praised by authors because they are attracted by its novelty or they wish to have their names connected with the recommendation of a new medicament. In the second stage the "bears" of the medical stock-market find an opportunity for attracting attention to themselves by decrying that which others have lauded to the skies, and thereby giving the editorial shears a second opportunity of cutting out the names of those who have written and are writing about the remedy in question.

Those of the profession who gave an instant's thought before using it, to the chemical composition of the drug which is now under consideration, realized at once that it must surpass salicylic acid in its power of producing aberrant and dangerous symptoms even when given in very small doses to the ordinary individual, or when administered to a patient having idiosyncrasy to either one of its parts, namely, salicylic and carbolic acids.

In the numbers of the *London Practitioner* for July and August, 1890, is a very interesting and able paper by Dr. Hesselbach, of Halle, in which this author considers the action of salol upon the kidneys in relation to its effects when given in poi-

sonous doses, and he has also recorded a case of a young man who took by mistake two drachms of salol, thereby producing death.

His conclusions, after quite a prolonged physiological and toxicological study, are as follows:

1. The large proportion of phenol contained in salol renders it so toxic a substance that its unrestricted therapeutic use is fraught with danger.

2. In renal disease, acute or chronic, salol is contra-indicated.

It should be remembered that when we administer salol that with every one hundred grains of the drug given we give no less than forty grains of carbolic acid, so that if this amount is used during the day an extremely large dose of a very lethal and irritating agent is ingested.

REVIEWS.

Saunders' Question Compends: Essentials of the Diseases of the Eye, Nose, and Throat. By Edward Jackson, A.M., M.D., and E. Baldwin Gleason, S.B., M.D. With 118 illustrations. Philadelphia: W. B. Saunders, 1890.

This book is the fourteenth of its series, and we understand that still others are to follow it, namely, one on Diagnosis, by Dr. D. D. Stewart, one on Practice, by Dr. Henry Morris, and one on the Diseases of Children, by Dr. Wm. M. Powell. Like its predecessors we can highly recommend this compend to students who desire such an aid, as we believe it is the best short epitome of the subjects of which it treats that we have. We are sorry that in the section on the eye so little is told us about correcting errors of vision by means of glasses, but the omission is excusable in so limited a space, and in a book arranged in this manner.

Dr. Gleason's part of the book is very well done, but we wish that the proof-reading had been more careful in all parts, although this book is better than some of its predecessors in this respect. Thus, on page 139, in the second paragraph, the word "failure" is used where the word feature is evidently intended, and in the endeavor to be concise clearness has sometimes been sacrificed to brevity, chiefly by the omission of "a" and "the." So many short books on the eye and throat are now on the market that no great sale can be expected for any of them, but if any succeed this one should do so.

Railway Surgery. By C. B. Stemen, A.M., M.D., LL.D. Illustrated. St. Louis: J. B. Chambers, 1890.

This book is an interesting evidence of the growth of railway surgery in importance. While it is a valuable contribution in this respect, it contains very little that cannot be found in general surgical text-books, and is disappointingly imperfect in some of its parts. The chapter on anæsthetics is wofully behind the times, particularly in view of the great prominence of this subject at the present day; and the advice given as to the treatment of shock possesses no particular advantages over any other treatment that we are familiar with, and is not as good as it should be. Finally, the book bears unmistakable evidence of having been dictated instead of written, and in consequence shows the ineffaceable evidences of hurry or carelessness, and lack of easy diction. Much of the work is copied *ad libitum* from other writers on the subject treated of, and while due credit is given in each instance, this causes a lack of originality.

CORRESPONDENCE.

CHICAGO.

To the Editor of The Medical News,

Sir: At a recent meeting of the Chicago Pathological Society, Dr. Homer M. Thomas read a paper on "Nasal Catarrh." After dealing with the physiology of the nasal passages and the etiology of the affection, he dwelt upon the symptomatology and referred to the presence of ocular symptoms in nasal disease as an interesting feature. A certain group of eye-symptoms, such as lachrymation, photophobia, conjunctival hyperæmia, are observed in a number of patients who go to rhinologists, and yet an examination of their eyes reveals no anomaly; the vision is normal, there is no eye-strain, the conjunctivæ are healthy, and the tear-ducts are open. In such cases relief of the coëxisting rhinal affection usually results in the cure of the eye-symptoms. An interesting case was reported. A woman was troubled with severe hypertrophic rhinitis, and stated that she had been unable to use her eyes longer than five minutes at a time for several years. The turbinated bones were well cauterized, after which the patient was referred to an oculist. She returned in two weeks, and stated that she had not been to the oculist, for the reason that after her hypertrophies were cauterized she was able to read at night without eye-symptoms.

Dr. Thomas said that the basis of the successful treatment of nasal catarrh is a thorough application of the principles of antisepsis. Given a case in which it is possible to medicate efficiently the anterior and posterior openings of the nasal passages as often as necessary, a cure can usually be produced. The nasal passages should permit the free entrance and exit of air during inspiration and expiration, and anything that interferes with this normal function is the starting-point of nasal catarrh.

Conditions may exist in the nasal passages which require surgical treatment, such as the straightening of a deflected septum, or the removal of portions of the superior turbinated bones. If there is an obstruction that interferes with free nasal respiration, there can be no successful treatment until the obstruction is removed. It has been estimated that out of six hundred people there are not more than ten who have perfectly straight and smooth passages; hence internal deviations of the passages are not a cause of disease, unless they interfere with perfect nasal respiration. Dr. Thomas believes that a great deal of unnecessary surgery is done upon the nasal passages, and that a large proportion of cases do not require any surgical procedures.

The remedies he advocates are strong astringents, strong solutions of nitrate of silver applied with a post-

nasal syringe, sprays of the tincture of chloride of iron, tannic acid, etc.

At the outset the nasal cavities are sprayed with Dobell's solution, or with listerine. Seiler's antiseptic tablets are also very effective; and albolene, too, is an excellent medicament. A powder which has been found very satisfactory in its action on the mucous membranes of the nasal organs, consists of one grain each of borate and bicarbonate of sodium, three grains of the carbonate of magnesium, four grains of cocaine, and a sufficient quantity of sugar of milk to make one hundred grains. This combination allays acute inflammatory attacks, and also temporarily relieves hypertrophies of the turbinated bones. Dr. Thomas uses it by insufflation, both anteriorly and posteriorly. The action of the powder seems to be due to its stimulation of the vasomotor nerves, causing contraction of the vessels of the terminal bulbs of the peripheral nerves and diminishing their blood-supply.

The Railway Brotherhood Hospital Association was chartered at Springfield a day or two since. Its object is to establish ultimately hospitals for the sole benefit of railroad men at convenient points between New York and San Francisco. It is expected that all the railroad brotherhoods will eventually come in and give the scheme their financial and moral support. A hospital in this city has already been secured. It is the old Bennett Hospital, on the corner of Ada and Fulton Streets.

Dr. John B. Chaffee, who has been a practising physician in Chicago for nearly a quarter of a century, and at one time one of the best-known practitioners in the southern part of this city, died at his home, September 7th. He came from New York State, and graduated at the McDowell Medical College in 1861. During the war he served as surgeon under General Sheridan, and was wounded on several occasions. His wounds resulted in lameness of his left side, which lasted until his death. The cause of death was brain and spinal disease, from which he had been suffering about two weeks.

Thomas Kelly, M.D., C.M., M.R.C.S., has been elected Professor of Medical Chemistry in the College of Physicians and Surgeons, and Dr. Frank B. Earle Assistant to the Chair of Practice.

Dr. James B. Herrick has been appointed Lecturer on Materia Medica and Therapeutics in the Woman's Medical College, and Dr. Edwin M. Smith Professor of Anatomy.

The Chair of Professor of the Principles and Practice of Medicine, in Rush Medical College, will be filled hereafter by Dr. Henry M. Lyman, in the place of the late deceased Dr. James Adams Allen; and the Chair of Professor of Physiology, by Dr. Harold N. Moyer.

Dr. Elbert Wing has received the appointment of Lecturer on Nervous and Mental Diseases and Medical Jurisprudence in the Chicago Medical College, Dr. Walter Hay, it is understood, having resigned the professorship of this chair at the close of the last lecture term.

The new medical society, recently chartered, and known as the Chicago Academy of Medicine, will, we are informed, soon begin its strictly scientific work. Among the incorporators are Drs. J. G. Kiernan, Harold N. Moyer, and S. V. Clevenger.

Professor I. N. Danforth recently returned from a trip to Berlin, where he attended the International Medical Congress. His remarks before the September meeting of the Chicago Pathological Society, relative to the social affairs and scientific work done by the Congress, were very instructive and entertaining.

According to our city medical directory, recently issued by Mr. J. Newton McDonald, there are in Chicago, 1621 physicians (including homœopaths, regulars, and eclectics), 27 chemists, 18 microscopists, 574 druggists, 147 nurses, 352 dentists, 18 pharmaceutical, medical, and dental publications, 5 dental colleges, 8 medical colleges (1 eclectic, 2 homœopathic, 4 regular, and 1 physio-medical), 3 polyclinics, 2 colleges of pharmacy, 3 colleges of midwifery, 23 charity and benevolent institutions, 19 dispensaries, 31 hospitals, and 9 training-schools for nurses.

NEWS ITEMS.

Medical Achievement in China.—It is said of Dr. Kerr, a medical missionary at Canton, that he has, in the past thirty-six years, treated over 520,000 patients, and has prepared twenty-seven medical and surgical books. He has trained one hundred medical assistants, chiefly Chinese. China now possesses one hundred and four hospitals and dispensaries, at which, in 1889, more than 348,000 patients received treatment.

Dangerous Public Baths.—The New York City public baths are located at points along the North and East rivers in close proximity to the outlets of sewers. As a consequence, many of the boys who patronize these baths have been reported as under treatment for ophthalmia due to the irritating effects of the polluted water. A preliminary report to the Board of Health tended to confirm the fact of this origin of the trouble, although further investigations show that the number of cases was greatly exaggerated.

La Grippe and Witchcraft.—The prevalence of influenza in Alaska last winter was the cause of many deaths among the natives. Witchcraft and superstition had full sway among them, and in one of the tribes a little boy, aged seven, the nephew of the chief of that tribe, was for some reason supposed to be responsible for the epidemic. It is alleged that after torture the child was about to be burned to death, but was rescued by a courageous white miner.

Typhoid Fever at Princetan, N. J.—The town authorities at Princeton and the College trustees have entered into an agreement to construct a system of sewerage. The College will bear one-half the expense of the original plant. Typhoid fever prevailed to a moderate extent during July, and by the townspeople it was feared that the disease might become epidemic, but on August 1st, the number of cases was known not to exceed seven, all of which were recovering, and that no new cases had developed within several weeks. Analyses of water and milk, suspected causes of the disease, were made, but with negative results. In the case of one suspicious dairy it was found that the cows were allowed to drink from a brook into which fecal sewage found its way, but the milk from that dairy,

after analysis, was declared pure. Although the sanitary status of the College is believed to be above suspicion, the introduction of a modern plant of sewers has been deferred until this outbreak indicated that a longer delay would be dangerous.

Law for the Prevention of Blindness.—The legislature of New York has adopted a law, the substance of which is given below, for the prevention of that element of the causation of blindness which follows ophthalmia neonatorum. The statistics of our institutions for the blind show that not far from one-fifth of all their cases arise from that disease, and the sufferers belong largely to a class of our population that is attended by midwives and untrained nurses. The New York law, which went into effect on September 1st, is as follows:

"Section 1. Should any midwife or nurse having charge of an infant in this State notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse so having charge of such infant, to report the fact in writing within six hours to the nearest health officer or some legally qualified practitioner of medicine of the city, town, or district in which the parents of the infant reside.

"Section 2. Any failure to comply with the provisions of this Act shall be punishable by a fine not to exceed one hundred dollars, or imprisonment not to exceed six months, or both."

Obituary.—The death of DR. JAMES MATTHEWS DUNCAN has been announced by cable as having occurred at Baden, on the 3d instant. He was the distinguished professor of midwifery at the St. Bartholomew's Hospital School, and a valued authority in the departments of gynecology and pediatrics. He was born in Aberdeen, in 1826, and the schools of Edinburgh were the scene of his labors and eloquent lectures during the first twenty-five years of his professional life. In 1877 he went to London, and became eminent as a professor, author, and consultant, although his name and fame were world-wide long before he left the Scotch capital.

—— SIR WILLIAM CARTER HOFFMEISTER, M.D., of Cowes, Isle of Wight, died July 29th, aged seventy-three years. He was for many years the attending physician of the Queen, the Prince of Wales, and of many of their relatives and descendants, not a few of whom were ushered into the world under the ministration of this eminent obstetrician and physician. He obtained the honor of knighthood in 1884, in recognition of these services.

—— DR. ROBERT W. JONES, Professor of Therapeutics in the College of Physicians and Surgeons of Chicago, died suddenly on September 12th.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 9 TO SEPTEMBER 15, 1890.

By direction of the Acting Secretary of War, a Board of Medical Officers, to consist of EDWARD P. VOLLUM, *Colonel and Surgeon*; GEORGE M. STERNBERG, *Major and Surgeon*; ALBERT HARTSUFF, *Major and Surgeon*; and WILLIAM E. HOPKINS, *Captain and Assistant Surgeon*, is constituted to meet in New York City, on October 15, 1890, or as soon thereafter as practicable, for the examination of candidates for admission to the Medical Corps of the Army.—Par. 8, *S. O. 213, A. G. O., Washington, D. C.*, September 11, 1890.

By direction of the Acting Secretary of War, JOSEPH K. CORSON, *Major and Surgeon*, is relieved from duty at Fort Sherman, Idaho, and will report in person to the commanding officer Washington Barracks, District of Columbia, for duty at that station.—Par. 4, *S. O. 212, A. G. O.*, September 10, 1890.

By direction of the Acting Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered:

HEIZMANN, CHARLES L., *Major and Surgeon*, is relieved from duty at San Antonio, Texas, and will report in person to the commanding officer at Fort Clark, Texas, for duty at that station, to relieve Edward P. Moseley, Captain and Assistant Surgeon, who, upon being relieved by Major Heizmann, will report in person to the commanding officer at San Antonio, Texas, for duty at that station.—Par. 23, *S. O. 211, A. G. O., Washington, D. C.*, September 9, 1890.

CARTER, EDWARD C., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month.—Par. 2, *S. O. 108, Headquarters Department of the Columbia*, September 6, 1890.

By direction of the Acting Secretary of War, NATHAN S. JARVIS, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Verde, Arizona Territory, and will report in person to the commanding officer San Carlos, Arizona Territory, for duty at that station.—Par. 2, *S. O. 208, A. G. O., Washington, D. C.*, September 5, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 13, 1890.

WOOLVERTON, THEORON, *Medical Director.*—Ordered to the U. S. S. "Philadelphia," September 15th.

PENROSE, THOMAS N., *Medical Inspector.*—Detached from the U. S. S. "Richmond."

GARDNER, J. E., *Passed Assistant Surgeon.*—Detached from the U. S. Fish-culture Steamer "Albatross."

DRAKE, N. H., *Passed Assistant Surgeon.*—Detached from the U. S. Coast-survey Steamer "McArthur," and ordered to the U. S. Fish-culture Steamer "Albatross."

BERRYHILL, T. A., *Passed Assistant Surgeon.*—Detached from the Hospital, Mare Island, Cal., and ordered to the U. S. Coast-survey Steamer "McArthur."

HEFFINGER, A. C., *Passed Assistant Surgeon.*—Ordered before Retiring Board, October 1, 1890.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM AUGUST 12 TO SEPTEMBER 6, 1890.

VANSANT, JOHN, *Surgeon.*—Granted leave of absence for thirty days, to take effect upon return to duty of Assistant Surgeon J. C. Perry, September 5, 1890.

WYMAN, WALTER, *Surgeon.*—To proceed to Cape Charles Quarantine Station, on special duty, August 25, 1890.

STONER, GEORGE W., *Surgeon.*—Granted leave of absence for four days, August 19, 1890.

CARMICHAEL, D. A., *Passed Assistant Surgeon.*—Leave of absence extended fifteen days, August 26, 1890.

AMES, R. P. M., *Passed Assistant Surgeon.*—To proceed to Memphis, Tenn., on temporary duty.

DEVAN, S. G., *Passed Assistant Surgeon.*—Leave extended five days, on account of sickness, August 12, 1890.

WILLIAMS, L. L., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, September 5, 1890.

GOODWIN, H. F., *Assistant Surgeon.*—Granted leave of absence for thirty days, August 21, 1890.

COBB, J. O., *Assistant Surgeon.*—To proceed to Marine Hospital, Detroit, Mich., for duty, August 16, 1890.

HUSSEY, S. H., *Assistant Surgeon.*—Granted leave of absence for thirty days, August 19, 1890.

PERRY, J. C., *Assistant Surgeon.*—Granted leave of absence for twenty days, to take effect when relieved, September 3, 1890.

YOUNG, G. B., *Assistant Surgeon.*—To rejoin his station, at St. Louis, Mo., when relieved, September 3, 1890.

APPOINTMENT.

ROSENAU, MILTON J., *Assistant Surgeon.*—Commissioned as an Assistant Surgeon by the President, August 25, 1890. Ordered to Chicago, Ill., for temporary duty, August 27, 1890.

ORIGINAL LECTURES.

MACEWEN'S OPERATION FOR CONGENITAL INGUINAL HERNIA.

A Clinical Lecture.

BY D. A. K. STEELE, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

GENTLEMEN: The patient we present to-day is this little child, with the following history: He is now eighteen months old. His mother states that soon after his birth she noticed a swelling in the lower part of the abdomen, appearing simultaneously over each inguinal canal. When the child was about three weeks old, it was seen that the swelling extended lower down; the mother noticed that the swelling increased along the course of the inguinal canal when the child made any violent effort, such as coughing, crying, straining, or any exertion that brought into play the diaphragm or abdominal muscles. Some weeks later she took the child to a dispensary, where a truss was adjusted, but the instrument did not prevent the reappearance of the swelling in the scrotum. During the past year a number of trusses have been applied, but none of them prevented the recurrence of the hernial swelling.

Now, when an infant is brought to us suffering from a tumor of the scrotum, it may be one of a variety of diseases, and it is well to make a diagnosis by exclusion. Let us enumerate some of the various tumors that may occupy the scrotal pouch. We may have either a hernia, hydrocele, epididymitis, hæmatocele, varicocele, œdema, or an orchitis, or a complication of two or more of these affections. How shall we differentiate these varied conditions? What will aid us in a correct diagnosis in a given case? For diagnostic or clinical purposes tumors of the scrotum may be divided into two general classes, namely: reducible and irreducible. The reducible tumors include all varieties of hernia (except strangulated), varicocele, and congenital hydrocele. Irreducible tumors include those connected with the testicles, all hydroceles (except congenital), and strangulated hernia. Tumors of the tegumentary surface of the scrotum, such as inflammatory œdema, elephantiasis, and epithelioma, are usually so characteristic in their history as to offer no special impediments to a correct diagnosis.

Scrotal hernia may be mistaken for (1) hydrocele of tunica vaginalis, or cord, or for encysted hydrocele; (2) sarcocele of the testicle, either simple, tuberculous, cystic, or malignant; (3) varicocele; (4) hæmatocele; (5) bubo or an undescended testis.

In scrotal hernia, as a rule, the tumor is soft and doughy to the touch, light in weight, smooth and regular, and painless, unless inflamed or strangulated. Its advent is sudden, and from above downward; it is resonant on percussion; fills the inguinal canal; has an impulse on coughing; and is of normal opaque color, and gurgles on pressure. It may exist on either side; the spermatic cord is concealed; the tumor does not fluctuate; aspiration gives negative results, and the bowels may be embarrassed. It can be reduced, unless the hernia is strangulated or incarcerated.

In hydrocele of the testicle the tumor is ovoid or pyriform; develops slowly from below upward; is firm, tense, and elastic; is translucent, fluctuating and dull on percussion, and is reducible. The spermatic cord is neither concealed nor displaced; the inguinal canal is empty; the bowels are unaffected, and aspiration reveals fluid.

In congenital hydrocele the fluid completely disappears within the peritoneal cavity if the tumor is compressed for a short time.

In sarcocele of the testicle the tumor is usually hard and resistant; heavy; often nodular and irregular; painful; grows slowly, and is dull or flat on percussion. The inguinal canal is empty; there is no impulse on coughing; the bowels are unaffected; the tumor is irreducible, and there are no auscultatory sounds. Simple sarcocele is a chronic orchitis, both the epididymis and body of the gland being affected, and the cord is usually thickened. Abscess of the organ may occur, and is usually caused by an injury followed by inflammatory deposits. Tubercular sarcocele is met with most frequently in early manhood, and may occur in any variety of constitution—in the strong and robust, as well as the weak and cachectic—and although often associated with tuberculosis of other organs, it is not uncommon to find the tuberculous nidus in the epididymis, not as a sequence of gonorrhœal inflammation or some slight injury followed by inflammatory infiltration, as was formerly believed, but as a coincident. The progress is slow and insidious. The gland at first moderately enlarges, with little or no pain, the hypertrophy being especially marked in the globus major. Presently the outline of the tumor becomes nodulated, and it extends around the testicle from behind forward. After several months, the adventitious tissue exceeds in size the testicle proper, and then it begins to soften, and one or more abscesses burst and discharge a thin, shreddy pus. The vas deferens is greatly enlarged.

In syphilitic sarcocele, or gumma, the history of the patient guides us in the diagnosis. We also find that the body of the gland is usually the seat of the infiltration which takes place in the connective tissue between the tubuli seminiferi, the epididymis undergoing little, if any enlargement. The cord and vas deferens are unaffected. There is little or no tenderness, and the peculiar sensation elicited by squeezing a healthy testicle is absent. The tunica albuginea is very greatly thickened. Hydrocele is a frequent complication, and tapping is often required to establish a diagnosis.

Cystic tumors of the testis closely resemble hydrocele, and differ chiefly in being opaque instead of translucent. Aspiration should be practised before pronouncing positively upon their character.

Cancer of the testicle primarily invades the body of the gland, and almost invariably assumes the encephaloid form. Most observers doubt the existence of other varieties of malignant disease in this organ. The development of the disease is rapid. The patient has a sensation of weight, pain, and dragging in the testis; the scrotum becomes distended, and reddish or purplish, and the superficial veins are enlarged. The skin adheres to the gland, ulceration occurs, fungous growths protrude, the inguinal glands are secondarily involved, and the patient by this time presents the characteristic cancerous cachexia.

In varicocele the tumor develops gradually; is knotty and irregular, like a bag of worms; is bluish in color, and is most frequent upon the left side. It increases in size upon the application of heat; is dull on percussion; fluctuation is doubtful, and the spermatic cord is not affected, nor is the inguinal canal involved. There is no cough-impulse. The tumor disappears when the patient assumes any position that favors increased venous return, but immediately returns when he stands up, notwithstanding pressure at the ring. There is a sensation of weight and dragging in the scrotum.

In hæmatocele the advent is sudden, and usually follows traumatism. The tumor grows from below upward, if it arises spontaneously; at first it is soft and fluctuating, but when coagulation occurs it becomes hard. It is pyriform in shape; ecchymotic, irreducible, heavy, and dull on percussion. The spermatic cord is unaffected, and the inguinal canal empty. There are often pallor and prostration from loss of blood. The bowels are unaffected.

Bubo is seldom mistaken for a scrotal tumor, and it is unnecessary to name the differential points.

An undescended testicle is painful, and pressure upon it causes a peculiar, sickening pain. The scrotum is imperfectly developed upon the same side, and, of course, does not contain the testicle. It is sometimes mistaken for bubonocele.

Now, gentlemen, I trust that this minute enumeration of diagnostic points may not be considered tedious or unnecessary, and that a remembrance of them will aid you in making a correct diagnosis.

Let us return to the patient before us. We have here a soft, elastic, compressible, reducible swelling, occupying both sides of the scrotal pouch; cough-impulse is present, and gurgling is plainly felt. Upon flexing the thighs, elevating the hips, grasping the scrotum gently, and making moderate compression, the tumor disappears within the abdominal cavity. Inversion of the bottom of the scrotum by the little finger enables us to follow readily the receding mass through the dilated inguinal canal and distended inguinal ring into the abdominal cavity. With the history presented, and with the result of this physical examination, we are enabled to make a diagnosis of *double congenital oblique inguinal hernia.*

Now, inasmuch as persistent efforts during the past year have been made by able surgeons to retain this hernia *in situ* by various trusses, without success, what plan of treatment shall we adopt? The treatment of the affection, as you know, may be divided into *palliative* and *radical*, or *curative*. Palliative treatment consists in the use of such apparatus, instruments, or trusses, fitting over the inguinal ring, as will prevent the extrusion of the hernial tumor. They must be fitted with sufficient nicety to the contour of the parts to inflict the minimum amount of pain, and yet with sufficient firmness to resist the intra-abdominal and intra-thoracic pressure produced by coughing, crying, straining during urination or defæcation, or any exercise of the voluntary muscles that causes downward pressure upon the abdominal viscera. In a large proportion of cases a properly adjusted truss, continuously worn during the first few months or year or two of infantile life, will effect a permanent occlusion of the distended inguinal ring; but occasionally we meet with cases, such as the one we have just examined, where cure by means of a truss is impossible.

If it is impossible to retain the hernia within the abdomen, then it becomes necessary to resort to more radical measures—to closure of the enlarged canal by means of a surgical operation. One of the best operations for this purpose is that devised by Macewen, of Glasgow.

Macewen's operation consists, first, in a thorough cleansing of the field of operation with soap and water, and removing by means of turpentine all animal oil from the surface. The parts are then covered with lint saturated with a bichloride solution. In the case of an adult, the hair of the pubes and neighboring parts is closely shaven. The patient is then anæsthetized, and the limb on the side of the swelling is flexed at the knee and retained in that position by a pillow placed beneath. After having reduced the bowel, the operator makes an incision sufficiently large to expose the external abdominal ring. An exploration of the sac and its contents is then made, and the finger introduced through the canal examines the abdominal aspects of the internal ring, and determines the position of the epigastric artery. The following steps of the operation may then be divided into two parts—the one relating to the establishment of a pad on the abdominal aspects of the internal ring; the other to the closure of the inguinal canal. The details are as follows:

The surgeon frees and elevates the distal extremity ot the sac, preserving any adipose tissue that may be adherent to it. When that is done, he pulls upon the sac, and, while maintaining the tension, introduces the index-finger into the inguinal canal, separating the sac from the cord, and from the parietes of the canal; he then inserts the index-finger outside of the sac until it reaches the internal ring, and there he separates the peritoneum for about half an inch around the abdominal aspects of the ring. Next, a suture is firmly secured to the distal extremity of the sac, and the free end is passed in a proximal direction several times through the sac, so that when pulled upon the sac becomes folded upon itself like a curtain. The free end of this stitch, threaded on a hernia-needle, is made to traverse the canal and to penetrate the anterior abdominal wall about an inch above the internal ring, the wound in the skin being pulled upward so as to allow the point of the needle to project through the abdominal muscles without pene-

trating the skin. The needles that Macewen uses are corkscrew-shaped, with an eye in the point, and are made rights and lefts. The thread is relieved from the extremity of the needle, when the latter is withdrawn, and is pulled through the abdominal wall; and when traction is made the sac is thrown into a series of folds, its distal extremity being drawn backward and upward. An assistant maintains traction upon this stitch until the introduction of the sutures into the inguinal canal, and when this is completed the end of the first suture is secured by passing its free extremity several times through the superficial layers of the external oblique muscle. The pad of peritoneum is then placed upon the abdominal side of the internal opening, where, owing to the abdominal aspect of the circumference of the internal ring having been freshened, new adhesions may form. The sac having been returned into the abdomen and secured to the abdominal circumference of the ring, the inguinal canal is closed outside of it in the following manner: The finger is introduced into the canal between the inner and lower borders of the internal ring; the threaded hernia-needle is then introduced, and, guided by the index-finger, is made to penetrate the conjoined tendon—first, from without inward, near the lower border of the conjoined tendon; second, from within outward as high as possible on the inner aspects of the canal. This double penetration of the conjoined tendon is accomplished by a single screw-like turn of the needle, when a single thread is withdrawn from the point of the needle by the index-finger; after which the needle, with the other extremity of the thread, is removed. The inner side of the conjoined tendon is therefore penetrated twice by the thread, and a loop is left on its abdominal aspect. The other hernia-needle, threaded with that portion of the stitch which comes from the lower border of the conjoined tendon, is guided by the index-finger into the inguinal canal, and introduced from within outward through Poupart's ligament and the aponeurotic structures of the internal and external oblique muscles. It penetrates these structures at a point on a level with the lower stitch in the conjoined tendon. The needle is then completely freed from the thread and withdrawn. The needle is now threaded with the suture, which protrudes from the upper border of the conjoined tendon, and is introduced from within outward through the internal and external oblique muscles on a level corresponding with the upper stitch in the conjoined tendon. It is then freed from the thread and withdrawn. There are now two thread-ends on the outer surface of the external oblique muscle, and these are connected with a loop on the abdominal aspect of the conjoined tendon. To complete the suture, the two thread-ends are drawn together and tied in a reef-knot; thus firmly uniting the internal ring. The same stitch may be repeated lower down the canal, if thought desirable. In adults it is well to do so. The pillars of the external ring are likewise brought together, and, in order to avoid compression of the cord, it should be examined before tightening each stitch. It is advisable to introduce all the sutures before tightening any of them. When this is done, they all may be drawn tight, and maintained so, while the operator's finger is introduced into the canal to ascertain the result. If satisfactory, they are then tied, beginning with the one at the internal ring, and taking up the others in order.

During the operation the skin is retracted from side to side to bring the parts into view and to enable the stitches to be fixed subcutaneously. When the retraction is relieved the skin falls into its normal position, the wound being opposite the external ring. The operation is, therefore, partly subcutaneous. When the canal has been brought together, a decalcified bone drainage-tube is placed with its one extremity next to the external ring, the other projecting beyond the lower border of the external wound. A few chromicized gut sutures are then introduced along the line of the incision in the skin. Iodoform is dusted over the wound, a small portion of sublimated gauze is applied, and over this a sublimated pad, held in position by an aseptic bandage. When the patient is laid in bed, a pillow is placed under his knees, while his shoulders are slightly raised, so as to relax the tissues about the canal. The temperature is taken night and morning, and the dressings are left undisturbed for from fourteen to twenty-one days, unless they are stained or the temperature is elevated.

From four to six weeks after the operation the patient is allowed to rise from the bed, but is not permitted to work until the end of the eighth week, and is further advised not to lift heavy weights until the end of the third month. Adults engaged in laborious occupations are advised to wear a bandage and pad as a precautionary measure, but in the majority of children the closure is so complete and firm that further treatment by a pad is unnecessary.

In the case of this little child, who is now under the influence of an anæsthetic, we will modify this operation, inasmuch as we have to deal with a congenital hernia in which the loop of bowel and the testicle occupy a common sac—there is no tunica vaginalis. After the preliminary incision, I will separate the sac from its connections; then open it transversely about an inch and a half above its distal extremity, and form the lower part into a tunica vaginalis by closing it with fine continuous catgut suture. The upper part of the sac is now pulled down as far as possible, split longitudinally behind, a portion of it closed around the cord, which is carefully preserved, and that part which is left is now dealt with as the sac of an acquired hernia; passing a stitch through its distal portion a number of times, so that it becomes folded up as a curtain. Then with the finger I separate the attachments around the circumference of the abdominal ring. I then pass a needle through the abdominal wall an inch above the ring, bringing the thread out, where it is held by an assistant. Traction upon this cord forms the intra-abdominal pad or boss—a firm buttress that resists the intra-abdominal pressure.

I now proceed to close the internal ring in the manner described, passing two or three sutures along the course of the canal, drawing them snugly together, yet not tight enough to strangulate the cord. A drainage-tube is now passed from the upper angle of the wound and brought down through a slit in the bottom of the scrotum, so as to afford perfect drainage. The parts are now irrigated with a 1-to-3000 solution of bichloride, the wound closed with interrupted catgut sutures, dusted with iodoform, and hermetically sealed with cotton and collodion, so as to prevent infection from the urine, which is liable to occur in the case of infants or young

children. In closing the wound in this way we reduce the risk of infection to a minimum. A heavy antiseptic dressing will now be applied, and covered with a starch bandage. The child will be kept as quiet as possible, small doses of camphorated tincture of opium will be administered from time to time, and the dressing will probably have to be changed every second day. The mother will be directed to keep the child lying on the left side as much as possible, so as to avoid soiling the dressing during urination. The operation on the left side will be deferred until permanent healing of the right has taken place—probably for two or three weeks.

[Note.—A week later the child was presented to the class, and showed primary closure of the wound, except at the upper angle and the scrotal button-hole through which the drainage-tube emerged. Slight suppuration had taken place along the course of the drainage-tube. The highest temperature was 100.5°, on the day following the operation; the second day it dropped to 98.5°, and remained normal, the child showing no symptoms or evidences of having undergone a serious or dangerous operation, the result so far being in every way eminently satisfactory.]

ORIGINAL ARTICLES.

CONTINUOUS DRAINAGE IN THE TREATMENT OF ASCITES—ABDOMINAL SECTION FOR INTESTINAL OBSTRUCTION.[1]

By T. A. HARRIS, M.D.,
of Parkersburg, W. Va.

I have been prompted by certain articles on the "Benefits of Successive Tapping in Ascites" to report my success with continuous drainage in similar cases. It seemed to me that the continuous drainage of serous effusion would prove beneficial in cases with no organic disease of either the liver, kidneys, or heart.

Case I.—In August, 1888, I was requested by a country friend to see Mrs. B., with him. The history of the case was that the patient had been delivered by my friend after a tedious labor, some five or six months before; that the placenta had been retained, and that he had introduced his hand into the uterus and delivered it. The patient had a slow "getting up," and had not been well since. Some three months after her delivery the abdomen began to enlarge. The enlargement was evidently ascitic. She suffered with soreness and tenderness over the abdomen. The secretion of urine was very scanty, but normal in character. When I saw her the abdomen was about as large as that of a woman at term. She was somewhat emaciated, but complained of nothing except the inconvenience and discomfort of the abdominal enlargement. Upon examination I could find no disease either of the heart, liver, or kidneys. She had had four children. She said that while carrying the last child she had had some soreness in the region of the right ovary; that when the doctor removed the afterbirth with his hand, it caused pain in the same region, and that afterward she was very sore over her entire abdomen.

I tapped her and drew off a large amount of ascitic fluid, a peculiarity of which was that it contained quite an amount of whitish flocculent matter. She was greatly relieved by the operation; the action of the kidneys was restored and she passed urine freely. But the dropsical effusion gradually returned, with the former symptoms, and in a month she was as large as before. I visited her again and found her in about the same condition as when I had first seen her. I then determined to make the second operation, if possible, more effective than the first. I had come prepared to introduce a drainage-tube, and to leave it in place. This I did, with the necessary antiseptic precautions. After introducing the trocar and canula I withdrew the trocar, and at once passed a drainage-tube through the canula. I then withdrew the canula and allowed the fluid to flow through the drainage-tube. About as much fluid escaped as after the first tapping. In order to prevent the drainage-tube from slipping in or out, I stitched it to a piece of adhesive plaster placed over the abdomen, and through which the end of the tube projected. Here I made my mistake, for in three days there was so much inflammation about the tube that it was necessary to remove it. Under simple treatment all the irritation quickly subsided, but there was again a return of the former trouble, so that in three weeks she was nearly as large as before. At the third tapping I determined that nothing should be lacking, and I left the tube in place with most careful antiseptic precautions. Three weeks from the date of the operation she travelled fifteen miles on the railroad to see me; the drainage-tube still in place. She said that the discharge for the first week had been quite free, but during the last two weeks much less. As there was still some discharge when she was in the recumbent position I did not think it best to remove the tube, and asked her to see me again in another week. She did not return until the expiration of two weeks, when she said that there had been no discharge for more than a week. I then withdrew the tube.

This was more than a year ago, and I have seen the patient several times since, once within the past month. She is well and has had no return of the trouble.

I know that "one swallow does not make a summer," and that one case does not establish a principle, but I have recently had a very similar case (October, 1889):

Case II.—I was again asked by a brother-practitioner to see a patient, and was given the general statement that the case was one of dropsy following confinement. On making the visit, I found an apparently healthy woman with an ascitic enlargement equal to that of the seventh month of pregnancy. She had been confined about four months before, and easily delivered of her fourth child. She was attended only by a neighboring woman. There was nothing unusual during her convalescence, but a few weeks later she noticed that her abdomen was

[1] Read before the West Virginia Medical Society, June 13, 1890.

enlarging. This did not at first cause her any uneasiness, as she said that she had noticed a similar, though slight, condition after the birth of her previous children. There was no discoverable disease of any of the viscera, and this fact, in connection with her statement as to enlargement after previous confinements led me to regard the effusion as due to some peritoneal irritation, if not to inflammation of a mild type; and I decided to try the effect of continuous drainage. With the usual precautions the drainage-tube was introduced through the canula and held in position by a strip of adhesive plaster, through which it passed and to which it was stitched. The case was left in the hands of my friend, who has since informed me by letter that the day after the operation he was summoned in haste to see the patient, and that he found her with a temperature of 102°, and a pulse of 110, and complaining of much pain over the region of the right kidney. The drainage-tube was all right and there was no abdominal pain. With warm fomentations over the region of the kidney and the use of an anodyne and antipyretic, the pain, the temperature, and the pulse were reduced by the next day, and from this time the course of the case was uneventful. There was some discharge from the tube for a few days, but by the end of a week there was none. The tube was retained for two weeks and then removed. There has been no return of the ascites; the patient is up and attending to the duties of a country housewife.

CASE III.—In July, 1888, I was asked to see a patient in an adjoining State, said to be suffering from dropsy. I found a woman whom I had seen several years before, on account of a uterine fibroid, and who was at that time in fair health, and suffering in no way from the tumor. I had advised against any operation for its removal, and told her that no medicine would be of any special advantage to her. Not satisfied with this advice, she had gone to a quack in a neighboring town, who promised to relieve her by medical treatment. She suffered much at his hands, from purgatives and diuretics, all to no purpose. She then fell into the hands of a homœopath, whose promises were about as futile as those of the quack.

When I saw her the second time she was so distended that respiration was seriously interfered with. I tapped, and drew off a large amount of ascitic fluid. The uterine fibroid was in its former place. The woman was in an extremely exhausted condition. I expressed the opinion that the fluid would again accumulate, and promised that if it did I would remove it, and make provision against its further return. In about a month I was recalled to the case, and found things about as at first, except that the patient's general condition was worse. I again tapped, introduced a drainage-tube, and left it in place. I did not see her again, but learned that the tube was effective in preventing any re-accumulation of fluid, but that there was some slight discharge until the time of her death, more than a month after the tube had been inserted.

CASE IV. *Abdominal section.*—I was sent for on March 9, 1890, to consult with Dr. William Kurn, of Lubeck, upon a case of obstruction of the bowels, in a boy of about fourteen years. The obstruction was of five days' duration, and there had been stercoraceous vomiting during the day. All reasonable and proper efforts had been made to produce a movement of the bowels.

I found a decided lump in the right iliac region, which was quite tender on pressure. There was a moderate amount of tympany. Under the circumstances I decided that there was but one thing to do, namely, to open the abdomen and find the cause of the obstruction. With the consent of the family this we did, at midnight, by the light of two small lamps, and in a log-cabin, from which we had to expel a crowd of people, several dogs, and a coop of chickens. The abdomen was opened with antiseptic precautions, by an incision over the lump in the right iliac region. The first thing that presented was the distended small intestine, which was healthy in appearance. Passing my finger in, I drew into sight the empty and flaccid ascending colon, and then the cæcum. Replacing these, I drew out the small intestine, working my way down toward the ileo-cæcal valve, when, after a little resistance, I drew out six or eight inches of deeply congested intestine. This was evidently the portion which had passed into the ileo-cæcal valve. Its withdrawal was attended with a gurgling sound, due to the rush of the contents into the cæcum. The obstruction was relieved. I then reversed my mode of procedure, and worked my way up the intestine as high as possible, and tried to force down with my fingers the contents of the distended small intestine into the colon. I found it easy to press onward the liquid contents, but the gas slipped through my fingers, leaving the small intestine about as much distended as at the beginning. I closed the wound with deep sutures of silver and superficial of silk, dressed it antiseptically, and put the boy to bed. He rallied well. I saw him again on March 13th, when I opened the dressing, and found the wound in good condition, excepting a superficial abscess just above the upper end of the wound. I cut the upper silk stitch, and let out about a teaspoonful of pus. After this the course of the case was uneventful. The bowels moved twenty-four hours after the operation, and continued open. Six weeks from the date of the operation, the boy rode six miles in a wagon to my office. He said that he was "well, and wanted to go to work."

I have reported this case in order to encourage early operations in cases of intestinal obstruction. I have seen a number of such cases, and this is the first that did not die. The operation was performed under very unfavorable circumstances as to time, place, and assistance, and yet was entirely successful. Why, then, shall we hesitate under more favorable circumstances, when the dire alternative of death stares us in the face?

In a case of intestinal obstruction I think that milder measures, such as purgatives, enemata, and massage, should be persisted in, *only* until the occurrence of stercoraceous vomiting, or of some other critical condition; then an exploratory incision

should be made, without reference to the obscurity of the diagnosis, for whatever condition the obstruction is dependent upon, there is little chance of recovery by other than operative treatment. Nor do I think the surgeon should stay his hand, let the condition of the patient be ever so desperate. Desperate conditions require desperate remedies, and in the average surgical mind I think that the operation is regarded as more desperate and dangerous than the facts warrant, when it is done with the precautions demanded by modern surgical teachings.

HYPNOTISM IN A RELIGIOUS MEETING.

By THEODORE DILLER, M.D.,
CLINICAL ASSISTANT TO THE CHAIR OF PSYCHIATRY AND NEUROLOGY, MARION-SIMS MEDICAL COLLEGE, ST LOUIS.

In a large tent in St. Louis, capable of holding 3000 or 4000 people, most extraordinary "religious meetings" have recently been held. These so-called "revival meetings" were led by one Maria B. Woodworth, who is, in my opinion, a paranoic of a strongly religious type.

The writer's attention was called to the subject by several of his patients, who averred that Mrs. Woodworth was a prophetess sent directly from Heaven, and that people were so impressed with her preaching that they were prostrated to the ground, and that while in this condition many had visions of heaven, angels, etc.

Together with Dr. Wellington Adams, I attended some of the meetings and found the statement to be correct that "people were prostrated to the ground," and I doubt not many had visions such as they describe. The meetings, for a time, increased in size, while the number hypnotized each evening increased proportionately. One evening the crowd in the tent was estimated at 5000 (many standing) while, it is said, nearly an equal number were turned away for want of room.

The beginning of the meeting is principally occupied by Mrs. Woodworth, who speaks to the audience. The address, for the most part, is an incoherent, unintelligible jargon, but occasionally a few sentences can be understood. The latter usually have to do with the supernatural occurrences related in the Bible, such as the Transfiguration, the descent of the Holy Spirit on the Apostles, or the miracles. Perhaps her favorite themes are the visions, especially those related in the Book of Revelations. She frequently interrupted herself (if such a discourse can be said to be interrupted) to tell of visions which she herself has had, or to describe one of the very many "cures" of physical ailments which have been effected by the "power" manifested in her meetings. Her address is usually very long and I noted that she never became excited nor did she have any tendency to "shout," or unduly elevate her voice, as is so common in the ordinary revival meeting. On the contrary, there was a quiet confidence expressed in her manner which was very suggestive of the delusional, self-conceited paranoic, strong in her own beliefs.

Toward the end of her discourse she begins to exhort her hearers to "Look up to the Lord"—"Hold up your hands"—"Have faith." Her followers obey her injunctions literally; they fix their eyes steadfastly on the electric lights high above them, or on the intricate mass of converging tent-ropes beyond. In this position a few of the more susceptible of her believers succumb. They go into the first or cataleptic stage of hypnotism while the exhorter is relating from the Bible or from her own experience the visions of heaven. A hymn then follows which is of a peculiar, monotonous character and well adapted to assist in promoting the hypnotic condition in many who are slightly or not at all influenced by the visual impressions alone. The hymn is usually repeated a number of times. During the singing, Mrs. Woodworth and her assistants (of which there are several) walk up and down the long platform encouraging those who are nervous, uneasy, or in any way visibly affected, to "hold up their hands, look up, and think of the Lord." The greatest number succumb during the singing.

As may be expected, more women than men are affected. At one large meeting the number more or less hypnotized must have been fully one hundred. Some were typical cases, exhibiting the three stages of hypnosis, namely, catalepsy, lethargy, and artificial somnambulism. When laid upon their backs on the platform, where the subjects were brought as rapidly as they became affected, those representing the typical condition lay with the eyes wide open, pupils dilated, and with a vacant or fixed stare; the arms unsupported extended upward and outward. One young woman whom I watched closely did not wink or move her eyeballs during the ten or fifteen minutes that I observed her. I attempted to place my finger upon her eyeball but was, in sharp terms, forbidden to do so by the attendant at her side. Many were more or less affected while on their feet; others while observing the directions of the leaders entirely failed in the consummation of their purpose.

A particularly shocking feature of the meetings was the hypnosis of children, of whom several were usually affected.

The force of example must have a strong influence with many. In Charcot's clinic the subjects for hypnosis are several times shown others in the hypnotic condition before any attempt is made to hypnotize them. This preparation causes a mental impression which makes the subsequent actual at-

tempts at hypnosis more generally successful and with fewer trials. Now most of Mrs. Woodworth's subjects have precisely this preparation: *i. e.*, they attend a number of meetings, become mentally impressed, and at subsequent meetings succumb with ease.

The question as to whether Mrs. Woodworth is an impostor or a case of religious insanity naturally arises. Judging from the meetings, from her autobiography, and more especially from an interview that I had with her, I am strongly of the latter opinion.

She states that she was born in 1845, in a small town in Ohio, but soon removed to Salem, in the same state. She denies inherited mental taint, but says that her husband was mentally unsound at one time. Four out of five of her offsprings died in childhood—one of "scrofula," another of some lingering malady.

She states that she never knew what the "power" was—never witnessed it until she had been engaged in evangelistic work for two years. When a child of thirteen she knew that the Lord had ordained her to go out and preach the gospel, and she became converted, but she fought against God. One day while sitting alone in her room she saw the vision of the Bible on the wall. The letters were raised and the book shone as brightly as the sun. This call to preach was an audible call, heard with her ears just as she hears anyone's voice now. After this she had many visions. At first the voice of God frightened her very much, but in time she became accustomed to it. The idea of going out to preach was so repugnant to her—because a woman—that she seriously contemplated suicide. A vision of the devil, who came and tempted her, also exerted a depressing effect upon her. Her lack of education, she also felt, was a serious obstacle. During this time of struggle and indecision the Lord came and persuaded her to go. She saw a bright light, too, and angels flying all around her.

She married at an early age. After marriage the struggle continued, and the devil came to tempt her, but the Lord told her that she must go out and preach or lose her soul. In this particular vision the Saviour was on the cross; his face was so bright that she could not see it distinctly. There was a crown of thorns at His feet. This vision occurred when she was at the age of thirty-four. She told the Lord of the difficulties which she felt were in her way—lack of education, etc., when the Lord gave her power to preach just as he had given it to the Galilean fisherman. She then began her work. During the first few years of her preaching no one was stricken down in the meetings, and she was frightened when she first saw the people fall down. In this extremity the Lord came to her again and said: "Sister, don't you remember the vision of the grain?" This vision she had beheld some time before, and was as follows: One day angels came into her room—"a whole flock of them." They carried her up and into the West, miles and miles away, over prairies and forests, and lakes and rivers. Then they stopped, resting in the air on their wings, and she saw a long, wide field of waving grain. She then began to preach, and saw the grain fall into sheaves. This she compares to Ezekiel's vision. Christ then came to her and said: "Be not afraid, that is the way you'll do when you preach to real people."

At present she seldom has visions except when "under the power," but frequently hears voices while sitting in her room, or while in bed, and she often converses aloud with the Deity. Her assistant or attendant states that she frequently finds Mrs. Woodworth standing in her room with fixed gaze and wholly immobile.

One evening during the progress of the meeting, Mrs. Woodworth herself became apparently unconscious, the condition coming on very gradually. But the phenomena in her case presented a marked contrast to those of her hypnotized followers. Instead of the expressionless, cataleptoid state common in them, the leader's appearance was that of great exhilaration—ecstasy. The face assumed a peculiar, radiant expression; the eyes became fixed, while the body remained immobile in a dramatic position. Her condition at that time was described as pure ecstasy. Her appearance was so striking, so supernatural that it would have impressed anyone. It is not a matter of surprise that the more susceptible of her followers are able to see at such times an actual halo of light about their leader's head. She may possibly at other times have attacks of catalepsy or hystero-epilepsy, but this I was unable to determine. Mills[1] states that the three conditions are commonly associated in the same individual.

The woman, I believe, is a case of *religious monomania* (paranoia). Her early struggles; her visions of hell and heaven; her strong temptation at one time to commit suicide; the nature, character, and evolution of her delusions, transforming the ignorant country girl into the undaunted, direct agent of the Deity—all confirm this theory. The two prominent characteristics of paranoia, namely, personal egotism and a feeling of persecution, are prominent features in the character of Maria B. Woodworth.

History is full of examples of religious characters such as hers. Spitzka[2] says:

"More than one insane fanatic of the middle ages has been responsible for the fierce campaigns waged against dissenters and alleged infidels, and not one of the least remarkable incidents of this period of history is the fact

[1] Pepper's System of Medicine, vol. v, p. 339.
[2] Manual of Insanity, p. 318.

that for two centuries Europe poured out its best strength in the Crusades, under the influence of the prayers, sermons, and visions of a Peter the Hermit, who undoubtedly suffered from this form of monomania."

Mills[1] describes a number of historical characters who, at times, would pass into the condition of ecstasy. Both Elizabeth of Hungary and Joan of Arc were cataleptics and ecstatics.

Gibbon's[2] description of the state of ecstasy as it occurred in the monks of the Oriental Church is classical.

The visions of Swedenborg and John Englebrecht were conceived during the ecstatic trance.

A notable case is that of Bernadette Soubirons, who, near a mountain stream of the Pyrenees, saw in the niche of a rock a female figure of great splendor, with an aureola about her head; her body also being very bright. She saw this vision a number of times, and believed it to be the Virgin Mary. The place has been made a shrine, and is visited by persons of all nationalities.

Cataleptic, ecstatic, hysterical, and allied manifestations in religious gatherings might be recounted at great length, but a few notable historical occurrences must suffice. The Buddhist fasts to render his body weak. He then fixes his eyes and thoughts intently on a single object, when he easily brings himself into the trance condition.

Often wonderful visions appear to subjects in the cataleptic state, and these are described to others.

The "dancing mania" occurred in 1374, principally in France and Germany. It is said that persons affected were unconscious, and insensible to pain, and that many beheld celestial visions. This epidemic was very widespread, the presence of one affected person being sufficient to excite the disease in a large crowd.

In the famous Kentucky revival of 1810 scores were prostrated at a single meeting. Some became cataleptic; others became possessed of a sort of "dancing mania" or "jerks." This latter manifestation was most remarkable. The body would sway violently forward and backward, the arms and hands striking out in any or all directions. The slave and his master, the delicate woman and the rugged backwoodsman, the preacher and his hearer, were alike affected.

The "jerks" appeared in Ireland about the year 1859, during the progress of a very remarkable religious movement. The manifestations were very similar to those of the famous Kentucky revival. Visions of various kinds were common, and thousands of persons were affected. An interesting feature noticed in many of the subjects was the appearance of stigmata on the hands or feet. For a description of those curious phenomena the reader is referred to the admirable articles of Hammond,[1] Clymer, and Mills.[2]

The reader of history—secular, medical, and religious—will find many more examples similar to those briefly referred to here.

These movements, or "jerks," of course, chiefly affect the neuropathic and hysterical or those predisposed to such conditions. Becoming more extensive the epidemic affects persons who are healthy, or at least who have enough mental and nervous stability to carry them through life, under ordinary circumstances, without abnormal manifestations of the nervous system.

Working upon religious feeling—the strongest in the human mind—is it to be wondered at that enthusiasts and religious monomaniacs have with their pseudo-religious fervor wrought such woful harm in the past? Who can estimate ultimate results in the way of hereditary transmission of nervous instability?

Laws governing the practice of hypnotism are now in force in Belgium, France, and Russia, and the writer hopes that efficient laws will soon be enacted in this country. An attempt on the part of Dr. Wellington Adams and myself to abolish the Woodworth meetings in St. Louis was futile, as there is no law by which that end could be attained. The cry may be raised by the unsophisticated and the ignorant that to forbid the Woodworth meetings would be a menace to religious liberty. To those we can answer that the law would not or should not permit the habitual use in religious exercises of agents, such as ether, chloroform, or opium, which will cause a person to lose consciousness. Neither should the use of a more subtle agent, such as hypnotism, be permitted. All these are universally recognized by physicians as exceedingly harmful in their effects when used habitually and indiscriminately, and by ignorant and unauthorized persons.

It should always be remembered that it is a serious matter to cause any person to lose his very *Ego*—through whatever agency.

The enlightenment of our age, and the scientific basis upon which hypnotism is beginning to rest, lead us to hope and believe that hypnotism as a factor in the hands of religious fanatics can never in the future do as much harm as it has done in the past.

Resignation.—Dr. George Strawbridge has resigned from the Chair of Otology in the University of Pennsylvania.

SUPPURATION OF THE TYMPANIC ATTIC AND PERFORATION IN SHRAPNELL'S MEMBRANE.

By B. ALEX. RANDALL, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EAR IN THE PHILADELPHIA POLYCLINIC; OPHTHALMIC AND AURAL SURGEON TO THE EPISCOPAL AND CHILDREN'S HOSPITALS, PHILADELPHIA.

The human drum-membrane is inserted into a grooved bony ring—the annulus or tympanic bone of the infant—which is incomplete above, where the auditory plate of the squamosa fills the gap between its anterior and posterior extremities or spines. This notch varies considerably in size and shape, giving considerable diversity to the appearance of the entire drum-head, but especially to the thin membrane which occupies it. This upper segment was first well studied by Shrapnell,[1] who described its "flaccid" character, and clearly differentiated it from the "membrana tensa" below, and it is now quite generally known by his name.

Rivinus had described, in 1689, an opening in this region (previously noted by Marchetti and others), and not a little controversy has raged as to the presence of a "foramen" at this point, Bochdalek and others claiming that it is a constant feature, although sometimes hard to discern; while some have almost denied its existence and insisted that it is rare and accidental. Hence the association of the name of Rivinus with this region, and the edge of the squamosa is often known as the "Rivinian margin" and an opening here as a "foramen Rivini." The embryological views of Huschke explained this opening as a colobomatous gap left by the incomplete formation of the drum-membrane across the bottom of the auditory canal; but modern studies have shown that no such formation takes place, since a complete septum between the external canal and the tympano-tubal fissure is present at all stages. While it is conceivable, therefore, that the foramen may in rare instances be congenital, since its bilateral presence has been associated with cleft palate and similar defects of growth, it is usually inexplicable on any such ground.

Within and above the flaccid membrane lies that portion of the tympanic cavity which lodges the larger upper portions of the malleus and incus. Leidy has brought into clear view the separate and variable character of this "recessus epitympanicus," and has most conveniently named it the "attic" in distinction from the other parts of the tympanum, the lower "atrium," and the posterior "antrum;" and Blake and others have shown the great variations in the bands within it, forming septa about the ossicles, as Politzer and Prussak had demonstrated the bands constituting the "pouches" in front of the neck of the malleus.

[1] London Medical Gazette, x. p. 120, 1832.

Crystallizing about this convenient name, "attic," much study has of late been given to the diseased conditions met in this locality; and the advocacy of the excision of the drumhead and ossicles in suppurative affections of the attic, has called for full investigation of the matter in all its aspects.

Moos seems to have been the first of modern otologists to describe (in 1864) suppurative perforation in Shrapnell's membrane, and a number of cases were figured by Hinton in his atlas (1874); but the studies of J. Orne Green (1874), Blake, Buck, Burnett, and Miller, in America, and of Politzer, Morpurgo, and Hessler, abroad, placed the subject in full view and left little for later students to add. Yet there are several points on which investigators are not in accord, and further study seems urgently called for; and as I have been directing attention to several of these of late, I beg leave to offer here the results thus far obtained.

The successful treatment of these cases is of course the special end of their study, and the questions of the origin, frequency, and seriousness of the lesions are of fundamental importance. If suppuration of the tympanic attic were rare, unimportant, or easily treated, much of the attention which has been given to it would seem misplaced; but there is evidence to show that it is by no means rare in aural practice, and I have elsewhere[1] given reasons for believing that aural affections constitute two per cent. or more of medical work. If not an element of much size in the practice of the physician, it makes up for it by its serious importance. It is not without cause that suppurations of the ear are bars to life insurance; and more often in these than in any others do we have caries just where the meninges are nearest.

The upper pole of the drum-membrane is often difficult to study owing to the narrowness of the canal or the configuration of its walls; and in any case the view is easily obstructed by flakes of epidermis, cerumen or inspissated discharge. Careful cleansing is often essential to the investigation of the Shrapnell membrane, and delicate and skilful manipulation of the probe and forceps is called for in order to clear the way. A considerable number of cases will then be found to present a depression of the membrana flaccida, with a clearly visible opening at its centre or a less certainly discernible foramen at the extreme upper margin. This is the so-called "foramen of Rivinus," and is met in about one out of five to ten cases. Its lack of physiological explanation has been already noted; while its persistence as a pathological perforation is readily comprehensible. Its symmetry and the lack of suppurative history may in some cases be cited in support

[1] Address in Otology, Transactions of the Pennsylvania State Medical Society, 1888.

of its congenital character: but any one who has seen much of ear-disease knows that the most interesting findings are often in the ear which the patient insists is not, and never has been, affected in any way, and will be a little sceptical as to the negative history. Most children have cried during an entire night with ear-ache, and timely study frequently shows in such a case a bulging or a perforation of the flaccid membrane. Cure is gained without sensible discharge, for only a single drop may have needed to be exuded in order to give immediate relief; so an otorrhœa is of course denied, as it sometimes is even when profuse. It seems a point worthy of note that I have rarely met these dry foramina in very young children; and I believe investigation would show them to be several times as frequent in adult life.

A further and more important point is clearly brought out by a routine study of the flaccid membrane. There is often a brownish scale covering the region and removable only with difficulty; and study will at once show that it is not cerumen, as may have been expected (the ceruminous glands do not extend thus far in), but a leathery crust similar to those formed in the nose. The exposed surface of the upper pole will be found red, perforated, and with a trace of moisture in the opening, barely enough to be wiped away, yet sufficient to renew the crust in a few hours. Opinions may differ as to whether these are to be regarded as cases of suppuration of the attic, since the scanty flow is of mucus rather than pus and some secretion is of course merely physiological; yet any extended observation will dash the hopes of anyone who expects these cases to remain quiet and innocuous. Sooner or later, upon slight occasion or without any really appreciable reason, an exacerbation will almost always take place that is unmistakably a suppuration of the attic. It is further noteworthy that the probe will detect bare surfaces of bone even in some of the dormant cases, the rough areas being usually either on the neck of the malleus or on the Rivinian margin. In not a few instances the loss of substance is not confined to the membrane, and a considerable opening will be found, due to loss of the bony margin, which exposes the head of the malleus if this be present, and opens the attic to view. Polyps, granulations or pearly masses of epithelium may fill the opening, and pus of a sickening odor be present in an ear that gave to the casual examination no evidence of disease.

So much for the external appearances in these cases. Within the tympanum important conditions are often present. If by any means the drum-cavity is inflated, there may be evident action upon the membrana tensa, and yet no perforation-whistle or other sign of exit of air through the opening at the upper pole. The intra-tympanic syringe may be vigorously used without carrying a drop of fluid to the pharynx through the Eustachian tube, although this may promptly result from injection into a lower opening in the same case. Morpurgo found that the air passed freely out through the normal flaccid membrane when incised; but could not be passed again until the engorgement due to the little operation had passed away. The reason for these things, as also for the limitation of disease to this small portion of the tympanum, has been well given by Blake and others who have minutely investigated the anatomical relations of these parts. Besides the ligaments of the ossicles, so well described by Helmholtz, numerous variable folds of mucous membrane are present, especially in this part of the cavity, which form septa dividing the area into more or less isolated compartments. From these the drainage is limited, yet usually sufficient; but it needs only a slight congestive thickening of these septa to close the avenues of escape for any retained secretion. Such a pouch was long since well described by Prussak as fairly constant between the flaccid membrane and the malleus neck. Politzer showed a series of such cavities in some of his preparations, while Kretschmann has shown that the form varies greatly, yet regards as most usual a pouch larger than that described by Prussak, and bounded within by the incus and its articulation with the malleus, as well as by the neck of that ossicle.

These isolated portions of the tympanum share in any inflammatory process, however caused, but they not infrequently fail to share in the resolution which may promptly take place below. The congestive occlusion of the Eustachian tube may be but transient, and the atrium recover its normal drainage before retained secretion has forced its way through the drum-membrane; but the attic, or a portion of it, be left congested and distended. Resorption or caseation of the secretion may follow; but resolution is apt to be imperfect, and a focus of future trouble formed.

The peculiar character of tympanic inflammations must not be lost sight of. The drum-cavity is lined with a delicate mucous membrane, readily involved by continuity in the catarrhal affections of the pharynx and nares, yet its inflammation is not a simple catarrh. It constitutes the periosteum of the ossicles and bony walls, and all except the superficial inflammations have some of the nature of a periostitis. Hence the ease with which caries can result from affections primarily catarrhal, for ulceration of the mucous membrane means denuding of the subjacent area of bone. The presence of a cheesy mass of retained secretion in contact with the neck of the malleus can hardly fail to be detrimental to the bone, and it is not surprising that lesions at this point are not rare.

Another fact in the anatomy explains the peculiar vulnerability of the Rivinian margin. The external part of the attic overhangs the auditory canal and is separated from it by only a thin wedge of bone dependent for its nutrition upon the mucous lining within and the delicate cutaneous covering without. These are the direct continuations of the flaccid membrane, are generally involved in its inflammations, and are all too ready to leave unnourished this thin *scute* to undergo caries or necrosis. Further, the suppurative process within the attic can gain partial exit at this point and burrow out sub-periosteally along the auditory canal, to form abscesses behind. before, or above the ear, sometimes involving most of the side of the head. The mastoid may be wholly uninvolved in these cases, although the abscess be on its outer surface; and a delicate probe may show that the fistulous track leads directly to the Rivinian region.

Inflammation of the tympanic attic probably occurs in almost all cases of otitis media, and in the larger number of cases shares the fortune of the general condition. Yet in a considerable group, conditioned doubtless by the anatomical variations above noted, the affection runs an independent course in the upper cavity. Shut off by the swelling of its lining from its usual communication, its pent-up secretion finds an exit through the thin, flaccid membrane, sometimes bagging it down into a long, polyp-like sac before rupturing it. Whether perforation of the membrana tensa, or even its total destruction, has previously taken place, matters little; the obstacle to drainage is above it, and even the total removal of the drum-membrane and malleus may not afford the requisite freedom of outlet. Drainage is usually bad, so that the ossicles and bony walls are extremely likely to suffer in the chronic cases. Treatment is difficult because access is imperfect: and the location of the process immediately below the meninges does not add to the comfort of the surgeon having such a patient in charge. Serious results are not uncommon; and without that, the exasperating obstinacy of many of these cases and their tendency to recurrence give them a most unwelcome reputation among aurists.

Part of this notoriety is hardly deserved. The bad cases are very bad; but there are many of less intense perversity and malign character, which are often earlier stages of the same condition, but much more amenable to treatment if promptly recognized and combated. Here lies almost all of what the writer can add to the previous contributions upon the subject. These attic inflammations with perforation in the Shrapnell membrane are not rare. Walb noted twenty cases among the 1231 patients of one year at the Bonn clinic; and Bezold, in Munich, eighty-eight among the 8227 patients seen in six years. In like manner at least fifty cases have been met by the writer among somewhat less than 2000 new patients treated during the past twenty months, although this record is probably incomplete. Numerous instances of dry perforations in this location, and of suppurations, suspected but not definitely proved to belong to this category, could be cited; but it is safer to accept the minimum figures, as they are sufficient to prove the frequency of the lesion. In point of fact, fifteen cases were met among the 500 seen in the first half of 1889, twenty-three among some 600 in the similar period of 1890, and seven among 100 patients in August, 1890, the periods during which strict records were kept. Only five were *noted as such* in my records for the latter half of 1889, although it is almost certain that more were seen; so I was prepared to admit that the earlier half of the year might show more cases, at least of the recent lesion. But this August experience would hardly bear out such a view.

The detailed histories of the cases seen in the first half of 1889, with five, previously noted and sketched, were presented at the meeting of the American Otological Society of that year; and the additional cases met up to July, 1890, were brought forward in the same place this year. Repetition of them here is quite needless. It may be well, however, to cite some details of a recent instance of the affection, in order to make clear some of their varying clinical features.

The certain recognition of the condition in question was made in this latest case only as these lines were being written.

Mr. H. P. was sent to me by Dr. Charles K. Mills, on August 26th, suffering with pain that for several nights had prevented sleep, accompanied by slight discharge from the left ear. Suppuration had been occasionally noted for several years, but the absence of any severe symptoms had led to neglect, since the hearing was little impaired except when the canal was clogged with discharge. A large polypoid mass was found growing from the upper wall of the canal about half way out and preventing any view of the fundus. Its removal was painful and had to be divided between several sittings, as the patient's endurance had been much reduced by his sleeplessness and sufferings; and the sinus around which, as usual, the mass had grown has not yet been followed to the uncovered bone which without doubt lies beyond it. The hearing was almost normal when the canal was cleansed, but the character of the lesion was suspicious, and the imperfect glimpses obtained of the Rivinian region increased the suspicion.

On September 5th the obstruction was so far removed that study became possible, and a considerable opening above the short process of the malleus was distinctly seen and the probe discovered carious bone within the attic. Intra-tympanic syringing with peroxide of hydrogen gave pain enough to

limit its employment somewhat, yet brought away much pus and cheesy secretion from the opening. The lower membrana tensa is thickened, somewhat opaque and macerated by the pus which has bathed it, but the hearing remains nearly normal, a fact which, however curious, is by no means unusual, although some authorities state the contrary. The patient has been quite comfortable since the first treatment, except for several hours after a deep cauterization with chromic acid, and has been able to attend to his work. He is satisfied with his condition, as well as with his progress, and is likely to demur decidedly if the caries of the malleus proves so considerable as to call for the excision which is becoming rather fashionable.

It seems here in place to comment upon the operation of excision of the malleus and drum-membrane, in cases such as these, of which Dr. Sexton is the most ardent American advocate. It rests upon the rational idea of removing carious bone and endeavoring to establish free drainage from the attic. The operation, though delicate, is not very difficult; but may be tedious from obstruction by bleeding. The tendon of the tensor tympani is first cut by a needle curved on the flat introduced close behind the short process and pressed upward until the slight snap of the tenotomy is felt and the malleus handle is found to move more freely outward. The drum-membrane is then divided around the periphery with a suitable knife and the malleus extracted by means of a snare loop around the handle. This last may prove difficult, as the placing of the loop is apt to be obscured by the bleeding, and the traction must be made inward as well as downward, lest the ossicle be broken through the neck. Probably the incus should be extracted before the malleus, as it is wholly useless in the absence of the first ossicle, and may, like it, be carious. Its disarticulation from the stapes must be delicately done, since dislocation of this last ossicle seriously imperils the hearing. As renewal in some fashion of the drum-membrane generally takes place, it is wise to carry the excision to the extreme periphery up and back, in the endeavor to prevent closure here by removing a part of the tendinous annulus. A portion of the chorda tympani is usually resected in such a case; but healing quickly follows, and the loss of taste on that side of the tongue is often unnoted by the patient during its brief duration. Little reaction is to be expected if proper cleanliness is observed—as an antiseptic the peroxide of hydrogen may be used in conjunction with styptic injections of hot water.

Such is the operation long in use by Schwartze and others, and of late most enthusiastically advocated, by Sexton especially. Its minor details are varied to meet individual preferences. It would seem to have given, in many instances, practical fulfilment of its theoretical value, but has yet to gain any wide acceptance among aurists. In the three cases of suppuration in which I have practised it the value was almost nothing, since the caries involved the Rivinian segment as well as the ossicles. Drainage seemed not appreciably improved, and in one case a new sinus formed above, while the suppuration continued freely from the lower opening.

In the less severe cases the process may often be brought to a halt by less radical measures; and while this cessation had best be esteemed as merely a hollow truce, it has been found to persist for two years or more in some cases, which is as much as can often be claimed for the operation at its best. The danger of these conditions naturally seems small to a patient who has had a suppuration for years that gives him little inconvenience; and, as before stated, the hearing may be practically normal and more likely to lose than gain by the operation. Consent to surgical interference may be wholly refused, and is apt to be accorded only in the worst cases. In these the results are not likely to prove brilliant; and while I expect to offer the interference to some of my patients, and even to urge it upon a few, it will be with no expectation of striking results or rapid cures. The cases in which these are at all possible, are those in which caries is limited to the ossicles and can be eradicated with them; and unless the diagnosis of such limitation can be made with much more certainty than is usually possible, the prognosis had better be a guarded one. Where the hearing is much affected and the presence of caries of the ossicles has been established, the chances of improved hearing and greater accessibility to the diseased structures speak in favor of the operation, since it is attended with little danger.

For the majority of cases the most thorough possible cleansing constitutes the best treatment. This will require painstaking care and some little skill, as the opening is apt to be too small to admit fluid except when the syringe-tip is carried directly into it. Enlargement of the perforation should be made when much difficulty of this kind is met, any granulations should be snipped off with the snare or forceps, and rough, bare surfaces of bone should be rubbed with the cotton-tipped probe in order to detach spicules and excite reparative inflammation. A long-nozzled syringe must be used in order to secure the needed penetration of the fluid—that of Blake serving admirably, although I use by preference a large lachrymal syringe with the hollow probe known as de Wecker's canula. The canula commended by Schwartze and Hartmann is generally too clumsily made and the curve at its extremity is oftener a danger than an aid. The delicate glass canula of Buck can be made by anyone at all skilled in working glass, and used with the fountain-syringe

or a bulb syringe worked by the patient, will do excellent service. It need hardly be reiterated that full illumination by the forehead mirror is essential to these manœuvres, which require a full view of the affected region, and generally the use of both hands.

In this connection it may be remarked that the construction of most forehead mirrors is very faulty in giving too limited a range of movement, and that one with a *double* ball-and-socket joint is far superior to that with the single, and enables the surgeon to get good illumination under the most difficult circumstances. The mirror may be brought very close to the eye, and looking through a large sight-hole, the advantages of central illumination may be combined with entire freedom from interference with binocular vision. The left hand may be used to make traction upon the auricle, draw forward the tragus and at the same time furnish a rest for the syringe—a very important item in the use of a piston-syringe.

The peroxide of hydrogen is probably the best fluid for intra-tympanic use, the twelve-volume solution being diluted with three to six volumes of hot water. Dizziness is but little more common under these measures than in the simple syringing of the canal, and can generally be avoided by gentleness and a proper temperature. The great value of the peroxide lies in its power to oxidize rapidly any purulent matter with which it comes in contact, and the resulting evolution of gas distends the cavity, forces the fluid into its remotest recesses and also aids in its evacuation. As this frothing, if active, may be disagreeable to the patient, the dilution is advisable, which also secures the desired warmth of the fluid. The delicate cotton-carrier will do good service in clearing the way before and after the syringing, and delicate forceps often are useful in removing detached flakes of epithelium, etc. The air-douche has but limited value in these cases, as before noted; yet it should generally be employed as a possible aid to the cleansing—due attention being paid, of course, to the naso-pharyngeal condition.

Numerous fluids have been employed topically in these attic suppurations with doubtful benefit. The nitrate of silver has undoubted value, but its employment is not free from risk except in weak solution, as is also the case with the mineral acids, which are credited with power to hasten the removal of dead bone. Boric acid in powder may be dusted into the opening or injected as a saturated solution, serving probably as well as any of the antiseptics accredited with more potency to keep the cavity sweet in the intervals of the cleansing.

Good results may be expected from this treatment in all the recent cases, and even among the chronic and carious affections gratifying improvement is common. Apparent cures may be quickly gained, yet relapses must be looked for in most of them, and the prognosis in the intractable cases is grave. In one of the patients reported in 1889 the attic affection remained in abeyance for some ten months, and started up only after a cold-taking which caused acute inflammation of both tympana. The caries of the malleus-neck and the growth of granulations from the Rivinian margin recommenced, and were slow in yielding to treatment, as they had also been slow to renewed activity.

The point to be especially insisted on in these, as in most aural suppurations, is the necessity of most painstaking cleansing at all times, in order that first the exact condition of matters may be recognized as promptly and clearly as possible, and second that the treatment may be applied, not to the exfoliated products of the inflammation, but to the affected tissues themselves. Thus only can we learn what we are dealing with, make sure that we are actually utilizing the measures undertaken for its relief and fairly compare the effects of various applications. It can be confidently predicted that the instances of attic suppuration with perforation in the flaccid membrane will be not infrequently met, under these circumstances, and that the shortcomings of the conservative treatment, properly applied, will not be found as great as the advocates of excision are inclined to claim. The serious, intractable cases will be found rather in the minority, since they will be attacked in the earlier stages; and the operative interference, confined to the instances which really require it, will be able to show its actual value in the cases not amenable to less radical measures.

Study of my fifty cases shows that all ages, from three to sixty-nine years, were represented, and that ten of the patients were less than ten years of age, while twenty-one were in the second decade. The perforation was in Shrapnell's membrane alone (as in Fig. 1) in twenty-three instances, being supplemented by a second opening or a cicatrix (Fig. 2) in the lower portion of the drumhead in a little more than one-half the cases. Polyps of notable size were present in almost a half, and caries was discovered in nearly as many. Destruction of the Rivinian margin (as in Figs. 6 and 8) had occurred in five cases, and loss of the malleus, and probably of the incus, in the same number. In one, the latter ossicle alone seemed to have been lost, and through the thin cicatrix which promptly formed in the posterior opening, the stapes and stapedius tendon could be plainly seen (Fig. 7). The perforation was usually in the central part of the flaccid membrane, above and before the short process, as in Figs. 2, 4, 5 and 7, less often involving the posterior part, as in Fig. 3 and to a less extent in Fig. 1.

FIG. 8.

The results of treatment cannot be fully and accurately stated. In fifteen of the patients the suppuration was brought sooner or later to a stop; and this apparent cure is known to persist after periods varying from two to twenty months, sometimes in spite of conditions which have set up suppuration of the other ear. For these it is fair to claim cure, with little reserve. In seven cases, on the contrary, the condition is known to be as bad as when first seen—in two of them, in spite of excision of the drum-membrane and ossicles. For the remainder, including the recent cases which are still under care, moderate success can be claimed. Many of them passed out of view apparently cured, but the maintenance of this condition cannot be asserted. Others were more or less improved, but uncured, when they ceased attendance. It can at least be urged, then, in favor of the less radical treatment that it rarely fails to bring about marked and often permanent improvement; and although recurrence of the trouble is common and always to be anticipated, that it may be rare and slight and with long intervals of immunity and apparent health.

MALIGNANT ŒDEMA.

(Gangrenous Emphysema; French, "Gangrene Gazeuse.")

BY K. HOEGH, M.D.,
OF MINNEAPOLIS, MINN.

A GIRL, eleven years old, was brought to me late on the night of June 28, 1890, with the history that, on June 25th, she had stepped barefooted on a nail in a barn, the floor of which was covered by manure and stable-soil. The nail caused a punctured wound of the right foot, about two inches behind the head of the second metatarsal bone. She complained of severe pain: there was very little bleeding, but the pain steadily increased, so that her sleep was disturbed. On the next morning the foot was considerably swollen, and there was marked redness of the dorsum and toes. During the second night her sleep was much more disturbed, and the pain increased to such an extent that she was in misery the whole day. The night of the 27th there was no sleep, and at three o'clock in the morning, about sixty-five hours after the injury, her mother noticed that the toes were "white as lard," cold, and insensible. Later in the day they were black. After a railroad journey of nearly one hundred and fifty miles, the child was brought to me, about eighty hours after the receipt of the injury. The foot was then black and gangrenous up to the tarsal bones. There was no suppuration, but small gas-bubbles were present; there was considerable œdema and a purplish discoloration up to the ankle, and above that streaks, as of lymphangitis, along the inner side of the leg, and some mottled redness in spots over the lower part of the leg. The original wound could not be seen. Her pulse was 120; temperature 101°. There was great pain; her mind was not quite clear, and she was in a condition suggesting collapse. As it was late, and I was not quite sure of the nature of the case and of the proper treatment, she was put to bed in St. Barnabas Hospital, with no other local treatment than elevation of the leg and permanent irrigation with an antiseptic fluid; whiskey was given, and also a hypodermic of morphine.

She passed a miserable night, and on the morning of the 29th her temperature was 103°; pulse very rapid. The gangrene had extended as high as the malleoli, and the œdema had reached to about two inches below the knee. In the presence of Drs. H. E. Holmes and E. Wood, house-surgeons to the hospital, and with their kind assistance I amputated the leg at the lower third of the femur, about four days and

four hours after the receipt of the injury. Careful antisepsis was observed, and the wound was drained with iodoform-tampons.

The amputated limb was carefully examined; the foot was black, as that of a cadaver that had been for a long time in water, and the epidermis came off like a glove. The corium was moist. Upon incising the foot no pus was found, but gas escaped. There was crackling, as of lung-tissue, when the soft parts were cut into. The track of the punctured wound was found; it was filled with a black coagulum. The œdema above the gangrene was very firm. Large quantities of greenish serum escaped after cutting into the leg. Here and there, over the gangrenous parts and the neighborhood, were large bullæ filled with a limpid fluid.

Two rabbits were inoculated with the serum and the contents of the bullæ, but, as their subsequent history proved, with no effect upon their health.

The night after the operation there was still some pain, but the patient was perfectly conscious. Her lips, as well as the skin generally, had a peculiar dusky appearance, which the mother declared was not the patient's natural color. She improved during the day; toward evening her temperature was 100°, pulse 90, pain less. From the next day recovery was uninterrupted. In about three weeks the patient went home well, and with a healed stump.

This case was diagnosed as one of malignant œdema or gangrenous emphysema (*gangrène gazeuse*), a disease of not very common occurrence. The characteristic signs and symptoms of this disease are a rapidly spreading gangrene, with the development of gases in the soft tissues, with no putrid smell, at least in the beginning, before contamination with putrefactive germs, and no formation of pus, but with marked constitutional intoxication manifested by fever and great depression of the nervous system. The local process goes on with rapidity and the constitutional symptoms increase *pari passu*. A case formerly observed by me terminated fatally on the sixth day. In the case described above the constitutional symptoms promptly disappeared after removing the infected limb.

The disease depends upon the presence of a specific bacillus, the bacillus of malignant œdema, which is described in Baumgarten's *Lehrbuch der pathologischen Mykologie*, 1890, from which the following notes are largely extracted.

In 1877 Pasteur described the bacillus under the name of *vibrione septique*, but the first complete and accurate description was given by Koch in 1881. The bacillus is, morphologically, very similar to the anthrax bacillus, with which it seems that Pasteur confounded it, but it has very distinct characteristics. It is more slender, the ends are rounded, and the bacilli are joined together in a somewhat different manner. It is further distinguished from the anthrax bacillus by having a spontaneous motility, a quality not belonging to the anthrax bacillus, as is well known. There are also differences in the spore-formation and in the behavior of these two bacilli in culture-media. The bacillus of malignant œdema is strictly anaërobic, and cannot live in the presence of oxygen. Biologically and pathologically, it is nearly allied to the tetanus bacillus, and like the latter its natural habitat is in the soil, especially in rich soil. It is very widely distributed, but it is questionable if it is found in uncultivated soil. It is found in the upper strata, but not on the surface, because it does not thrive in the presence of light and air.

Garden-soil seems to be particularly rich in these bacilli, just as it is in tetanus bacilli. Accidentally, they are taken into the animal organism, but do not produce spores during the life of the animal. After the death of the animal they multiply in the body. Like the tetanus bacillus the œdema bacillus not uncommonly invades horses, usually with fatal effects.

Pure cultures of this bacillus, when inoculated in animals, produce an extensive œdema, but do not produce gaseous gangrene. Inoculation with garden-soil, however, produces gaseous gangrene, probably owing to the simultaneous inoculation of the "pseudo œdema-bacillus." Nearly all domestic animals, mice, guinea-pigs, and rabbits are susceptible to these inoculations; only the cow seems to be exempt. To produce the disease the inoculations must be subcutaneous, as surface-wounds cannot be infected, and the quantity used must not be small. Injections into the bloodvessels give negative results.

After inoculation the œdema is apt to spread to the deeper parts, and unlike the anthrax œdema, is sanguinolent, not gelatinous. Inoculated animals occasionally survive, and the inoculation produces a decidedly less malignant infection than that caused by the anthrax bacillus. If an animal is killed and examined immediately, the bacilli are found only in the œdema of the superficial parts, never in the blood; thus resembling also in this the tetanus bacillus, and differing from the anthrax bacillus. A further similarity to the tetanus bacillus is the fact that one attack of the disease does not produce immunity against new infection.

If animals are inoculated with garden-soil malignant œdema and tetanus are common results, but the longer the earth has been dried the less is the probability that it will cause malignant œdema. The tetanus bacillus, however, or its spores, will retain their virulence in dry earth for almost an unlimited period.[1]

The so-called "pseudo œdema-bacillus" is commonly found accompanying the œdema bacillus, both in soil and in infected animals. These bacilli are, morphologically and biologically, easily distin-

[1] Faber on Tetanus. Copenhagen 1890.

guished from each other; the pseudo œdema-bacillus is anaërobic, and produces a gas, owing to its strong fermentative qualities. It seems probable that, biologically, these two bacilli may be to some extent dependent upon each other: for instance, by creating products of mutual benefit. Their strongly anaërobic qualities seem to make such an assumption possible.

Experiments in regard to the resistance of these bacilli and their spores, to our usual chemical antiseptics may have been made, but, if so, their results are not generally known. The experiments of Faber[1] prove that the tetanus bacillus is not destroyed by five-per-cent. carbolic acid solution nor by a 1-to-1000 sublimate solution, but only by heat.

Thus we have an explanation of the fact that punctured wounds have always been considered dangerous; we know now why such wounds, if they are infected by earth or by dust from the soil may be followed by tetanus and malignant œdema. Sufficient disinfection is not only difficult, owing to the narrowness and depth of the wound, but also to the fact that at least one of the bacilli which lurk in the soil is unusually resistant to chemical antiseptics. Hence, it becomes our duty to treat each punctured wound, which may be thus contaminated, in the most radical manner. After producing artificial anæmia by means of Esmarch's apparatus, the wound should be laid freely open, when it can then be seen and examined to the bottom. After removing foreign bodies, thorough cauterization with a galvano-cautery or hot iron is recommended, then ordinary antiseptic dressings. If tetanus develops experience has proved the inutility of amputation; but in a case of malignant œdema we should not hesitate to sacrifice a limb, as amputation may save the life of the patient.

MEDICAL PROGRESS.

The Treatment of Phthisis with Boric Acid.—For five years Dr. Gaucher has been studying the action of boric acid on pulmonary tuberculosis. He at first determined by means of experiments on animals the toxic limits of the drug, which he found to be in the ratio of about fifteen grains to each two and one-half pounds of the body-weight. He also found that it was eliminated rapidly by the kidneys, and that there is little danger of its accumulating. It is also eliminated by the lungs, and can be found in considerable amounts in the sputum of patients who are taking the drug.

Some of his experiments are interesting, and should encourage a careful trial of boric acid in the treatment of phthisis. For example, he injected with a hypodermic needle a few drops of a pure culture of tubercle bacilli into the lungs of several rabbits. In this way he set up a local tuberculosis, which soon became caseous, but not generalized. Some of the animals died from pulmonary tuberculosis, others were killed, and in all pulmonary phthisis was found at the autopsy. He then repeated the inoculations on healthy rabbits, but fed them on bran mixed with boric acid. After a time these animals also were killed, but in all the lungs, as well as the other organs, were quite free from tuberculosis.

As to clinical results, treatment with boric acid caused a notable diminution in the expectoration, which became more fluid and less purulent. Considerable time is, of course, necessary before the final results can be determined, but in the cases under observation it may be said that they improved in every way, while the tubercular disease in the lungs seemed to be at a standstill. The amount administered in these cases was fifteen grains, in divided doses, in twenty-four hours. As a rule, it will be found not to disorder the stomach, and in some of Dr. Gaucher's cases it seemed to check diarrhœa. As it has no disagreeable taste it is easily taken.—*Lancet*, August 16, 1890.

Antiseptic Treatment of Scarlatina.—According to the Paris correspondent of the *Archives of Pædiatrics*, Professor Hutinel has endeavored to determine the cause of the various complications of scarlet fever. His studies lead him to believe that these complications are due to secondary infection, and that the causative germs enter through the pharynx. If these hypotheses are true, the first indication in treatment is disinfection of the pharynx, and on this principle Dr. Hutinel has treated a number of cases with good results. As children cannot gargle, he uses irrigation by means of a large enema-syringe, through which a three-per-cent. boric acid solution is injected into the pharynx several times daily. He is careful to use a separate canula for each patient.

In addition to this, the throat is cleansed by mopping with a cotton tampon saturated with borated glycerin, and a few drops of borated vaseline-oil are dropped into the nostrils several times each day. The diet is confined to milk alone.

In 35 cases of scarlatina treated in this way there was 1 death. As to complications, 6 of the cases had albuminuria, 1 had rheumatism, 1 pleurisy, 1 otitis, and 1 diphtheria, but all the complications were promptly cured.

Creolin as an External Application in Inflammation.—Staff Surgeon v. Kobylecki (*Wiener medizinische Presse*, August 17, 1890) writes enthusiastically of creolin as an external application in inflammation from various causes. In a case of fracture at the ankle, which, when it came under his observation some hours after the injury, was ecchymotic, and very much swollen, applications of creolin in water reduced the swelling in four days. Since then he has used creolin-water in all cases of inflammation of the joints resulting from contusion or sprain, saturating the dressings every two hours or oftener, and always with good results.

In orchitis and epididymitis the applications are also of great benefit, and diminish the duration of the disease. In these affections the patient should remain in bed with the scrotum elevated, and should paint the latter once daily with pure creolin until recovery ensues. No other

[1] Loc. cit.

treatment is necessary, and, unless the application is made too often, no irritation is produced.

Hypodermic Injection of Bichloride of Methylene in Typhoid Fever. Hypodermic Injection of Chloroform in Strychnine-poisoning. — In *L'Union Médicale*, August 19, 1890, MARTINEZ reports from Zapateca, in the Republic of Colombia, the following interesting cases. In the first, tetanic contractions came on during the course of typhoid fever, and were cured by the hypodermic injection of bichloride of methylene; and, in the second, poisoning by strychnine was relieved by the hypodermic injection of chloroform.

A man, aged twenty-two years, of a strong, robust constitution and sanguine temperament, was attacked with a low form of typhoid fever complicated by well-marked tetanic spasms associated with trismus, the contractures affecting the upper and lower limbs and the muscles of the body, and being accompanied with constipation and retention of urine. The attacks came on at frequent intervals and lasted about five minutes. Dr. Martinez had recourse at this time to hypodermic injections of bichloride of methylene, giving from twenty to thirty minims. After the first injection there was appreciable improvement. The use of the bath to control the temperature, and the application of affusions to the nape of the neck to diminish congestion and relieve pain in the head, were also followed by favorable symptoms. The patient was given, in addition, bromides and chloral to allay pain and nervousness. He took his nourishment well, and passed a comfortable night. Soon afterward he had a copious movement from the bowels, and passed urine freely. Rapid convalescence set in and the cure of the entire attack ultimately resulted, the chief cause of relief being, in the author's mind, the use of the hypodermic injections, without which the convulsions would have killed the patient.

In the second case, one of strychnine-poisoning, a man, about twenty-eight years of age, married, but separated from his wife, for various reasons became desperate and resolved to attempt suicide by the use of strychnine. A quarter of an hour afterward he confessed to having taken the poison, and was immediately put to bed. The convulsive movements became severe. The treatment consisted in the hypodermic injection of fifteen minims of chloroform, followed by washing out of the stomach. Recovery ultimately took place, and, although at one time bromide of potassium and chloral were freely used, the reporter believes that the chloroform was the principal agent in producing a cure.

Chloroform Liniment.—

R.—Chloroform	4 ounces.
Camphor	1 ounce.
Fluid vaseline, sufficient to make	8 ounces.

Dissolve the camphor in the chloroform and then add the fluid vaseline. Of course, the amount of vaseline may be varied according to the strength of the liniment desired. It is said that this makes a much more useful application than chloroform liniment made with olive oil.

Gunshot Wounds of the Stomach and Intestines.—SENN (*Journal of the American Medical Association*, September 6 and 13, 1890), in a valuable paper on gunshot wounds of the abdomen, draws a number of conclusions, of which the following are the most important:

1. In gunshot wounds of the abdomen, in the absence of fæcal extravasation or prolapse of the omentum, it is absolutely necessary to determine whether penetration has taken place, by enlarging the wound.

2. Absence of visceral lesions requiring abdominal section is most frequently met with in perforating gunshot wounds of the abdomen if the wound of entrance is at or above the level of the umbilicus, and if its course is antero-posterior.

3. In transverse and oblique gunshot wounds at a point below the level of the umbilicus, multiple perforations of the intestines are extremely probable.

4. The general and local symptoms, with the exception of external fæcal extravasation, are absolutely of no value in the differential diagnosis between simple penetrating gunshot wounds of the abdomen and those complicated by visceral lesions.

5. Dangerous internal hæmorrhage caused by perforating wounds can be recognized by the symptoms of acute anæmia and by the physical signs of fluid in the peritoneal cavity, and such symptoms and signs are positive indications for abdominal section.

6. After opening the peritoneal cavity for the treatment of hæmorrhage, temporary hæmostasis should be secured by digital compression of the aorta, or by packing with sponges, until the bleeding points can be found.

7. Wounds of the stomach and intestines large enough to permit the escape of the contents of these organs can be infallibly demonstrated by the hydrogen test before the abdomen is opened.

8. Direct distention of the stomach through an elastic tube is preferable to rectal insufflation, when it is probable that the stomach is wounded.

9. Thorough insufflation, without evidences of free tympanites or escape of gas through the external wound, proves either the absence of perforations, or that, if present, they are too small for leakage to take place, and is a strong argument in favor of non-interference.

10. The hydrogen test should invariably be used in searching for perforations after the abdomen is opened, as this test makes extensive eventration unnecessary, and never fails to reveal every perforation.

11. After the lowest perforation has been discovered by rectal insufflation, the succeeding tests should be made through the perforations, and the external wound should never be closed until the entire gastro-intestinal canal has been tested.

12. The hydrogen test ordinarily does not cause fæcal extravasation.

13. By following the indications furnished by the test the surgeon relieves himself of all medico-legal responsibility in the operative treatment of gunshot wounds of the abdomen.

14. The closure of bullet wounds of the stomach and intestine is accomplished most speedily, and with a sufficient degree of safety, by one row of interrupted seromuscular sutures of fine aseptic silk. The operation should be undertaken as early as possible.

15. If enterectomy is unavoidable, the continuity of the intestinal canal should be restored by making lateral

anastomosis between the closed ends by means of decalcified, perforated, moist bone-plates.

16. Flushing of the abdominal cavity is to be reserved for cases in which the peritoneum has been contaminated by the escape of the contents of the stomach or intestines.

17. Drainage is necessary if the peritoneum has become infected, and in wounds of the kidney, spleen, or pancreas not treated by partial or complete extirpation. Also in wounds of the liver.

18. The necessary diagnostic skill and manual dexterity in the operative treatment of gunshot wounds of the stomach and intestines can be acquired only by experiments upon the lower animals.

Intravenous Injections of Quinine in Malaria.—Baccelli publishes (*Berliner klinische Wochenschrift*, June 2, 1890) an interesting communication on the intravenous injection of quinine in malaria. Believing that if the specific medicament was brought into direct contact with the blood-cells the destruction of the parasite would be accomplished more quickly and more permanently, he undertook a series of investigations to determine the following points:

1. The minimum dose which is required for complete and permanent cure.

2. The proper moment for the use of the medicament to prevent the paroxysm, to restrict it as much as possible, or to prevent a return.

3. The histological modifications brought about in the blood, already altered by the infection, through contact with the medicament.

In medical literature he found no example of injection of quinine into the vessels for therapeutic—that is to say, for antimalarial—purposes, although many physiologists had practised this expedient for purposes of investigation. The latter had, however, used acid solutions, and the author's investigations upon animals led him to believe that such solutions are extremely dangerous. Under these circumstances he employed a neutral solution of quinine hydrochlorate in distilled water with the addition of sodium chloride, to obviate the destructive action of the water upon the red blood-cells. The formula is as follows:

Quinine hydrochlorate	1.00 gramme	(15 grains).
Sodium chloride .	0.75 "	(11½ ").
Distilled water . .	10.00 grammes	(2½ drachms).

This solution is perfectly clear if employed lukewarm.

Having ascertained from repeated experiments that doses of five and ten centigrammes were perfectly harmless to guinea-pigs, the author employed the same doses upon man. After the veins of the forearm had become turgid, as the result of compression with a circular bandage above the elbow, he injected the solution with a Pravaz needle, inserted from below upward into the interior of one of the smallest veins, and immediately removed the bandage. The most rigorous antisepsis was observed, the solution being filtered and again boiled. The injection was made slowly, in order to observe that no swelling of the subcutaneous tissue took place, and, therefore, to be sure that the needle was in the interior of the vessel. The point of puncture was closed with collodion.

With the exception of one case, in which a number of abscesses developed, no injurious local effect resulted in any of the experiments. In two cases, in which the needle was not properly inserted into the interior of the vessel, and in which the solution was therefore partially injected into the subcutaneous tissue, there was œdema of the arm, but no other evil consequences. With doses of from ten to thirty centigrammes, no noteworthy physiological effects were observed. After the employment of from thirty centigrammes to one gramme, in three cases some of the characteristic symptoms of quinine intoxication immediately developed, namely, bitter taste, vertigo, loss of consciousness; at first a small and infrequent, afterward a fuller and slower, pulse-beat; and coldness of the skin. In general this condition disappeared in from fifteen to twenty minutes. In but a single case was cardiac weakness prolonged for several hours, so that the employment of cardiac stimulants became necessary. The usual dose of the quinine solution was from forty to sixty centigrammes. The results were good in so far as that, in many cases, the fever was at once brought to an end; and, if this were not done, there was always produced a diminution of the temperature succeeding the injection, frequently as much as 2° C. With doses of one gramme, in none of his patients was there a genuine recurrence of the attack under eight days. The author believes that when there is no idiosyncrasy against quinine, as much as three grammes of the solution can be injected into the veins without danger.

The great value of the method is in pernicious fever, for in other cases of malarial fever the ordinary methods of administration of quinine are usually efficient. In pernicious fever, one gramme of the solution should be the tentative dose. Of this form, 5 cases were treated by Baccelli with good results. Of these, 3 were of the somnolent variety, 1 was associated with hemiplegia, and 1 with bulbar symptoms. In addition to the quinine injections, analeptic and cardiac remedies were administered, especially repeated injections of ether, in large doses—five to ten grammes in twenty-four hours. The effect of the specific treatment in these cases was shown rather by the disappearance of the dangerous symptoms than by reduction of temperature, for in such cases temperature is frequently moderate, or even remains normal (*larval malaria*). In general, the following results were noted: The injections did not prevent or modify the fever paroxysm, if made at the acme, at the beginning, or even as many as three hours previous to the access. If made at the end or during the decline of the paroxysm, the succeeding paroxysm was either entirely prevented or much reduced in intensity. In the sub-continued forms of fever, which are usually rebellious to medication, it was found useful to make the injection during the period of remission, the effect being to transform the type into that of an intermittent, usually with an accelerated crisis.

We would especially call the attention of practitioners in the Western and Southern States of the Union to this important research, which seems to furnish them with a better method of combating the pernicious forms of malarial infection than has yet been at command.

EXOPHTHALMIC GOITRE.

WHEN the classical triad of symptoms—rapid heart, protruding eyeballs, and enlarged thyroid gland—is present, nothing is easier than the diagnosis of the affection to which English authors attach the name of Graves, and German writers that of Basedow. Quite different is it, however, if one or more of these signs should be absent or so slight as to escape notice unless searched for. The writer of this article remembers very well a case in his early practice which he mistook for phthisis on account of the repeated occurrence of hæmoptysis; and he has now under his care a case also attacked by pulmonary hæmorrhages, which had been variously diagnosed as phthisis, nervous dyspepsia, and hypertrophy of the heart. These two cases further agreed in the absence of exophthalmos, and in the fact that the thyroid enlargement was not perceptible upon casual observation, being hidden by the clothing of the patient, and very slight withal.

The early recognition of the affection, however, is a matter very often of prime importance; for it may be stated that, as a rule, the favorableness of the prognosis as to cure varies inversely with the duration of the disease. The difficulty of diagnosis is sometimes as great when the goitre presents itself as a prominent symptom, as when the goitre must be sought for; the most important of the three symptoms being the disturbed condition of the heart. In any case of overacting heart, especially in a neurotic subject, and more especially when associated with other phenomena of vasomotor ataxia, Graves's disease should be taken into consideration in the diagnosis and should not be lightly excluded. Even in the absence of demonstrable goitre, a thrill felt within, or in the immediate neighborhood of, the suprasternal notch, associated with a soft systolic blowing murmur, though not pathognomonic, is significant. When this symptom is found, careful observation will often bring to light the existence of a condition of intermittent enlargement of the thyroid gland, which would render the diagnosis certain.

SEELIGMUELLER (*Deutsche medicinische Wochenschrift*, May 29, 1890) has collated the most recent observations upon the symptomatology, pathogenesis, and therapy of the disease. According to this author, tremor, to which attention was first directed by Charcot in 1883, has assumed considerable importance as an initial symptom; thus Lewin observed it in thirteen out of twenty-seven cases as the first manifestation of the disease. One of his patients, a boy of nine years, after a severe fright suddenly exhibited muscular trembling and stuttering speech, while the full clinical picture of exophthalmic goitre did not present itself until the patient reached his seventeenth year. In the case of an hysterical girl, seventeen years old, who came under the writer's care at the medical clinic of the Jefferson Medical College Hospital, nystagmus had existed since childhood; goitre and cardiac disturbance suddenly developing after a fright consequent upon a fall from a step-ladder. In this case exophthalmos developed under observation.

Diminution of electrical resistance of the skin, first observed by Vigouroux and confirmed by Charcot, Eulenberg, von Martius, and Kahler, while not pathognomonic is an important symptom. It is plausibly attributed to increase of moisture the result of insensible perspiration. Irregular temperature is another indication of vasomotor instability which may be an aid in the diagnosis. Complications with epilepsy, tabes, ophthalmoplegia externa, irregular bulbar paralysis, polio-encephalitis, paralysis of the limbs, diabetes, polyuria, hysterical paralysis, etc., are reported. The importance of hysterical symptoms in diagnosis has long been known.

Of the more recent theories of pathogenesis, only

two demand attention: that which places the origin of the affection in the medulla, and that which seeks it in the thyroid gland. Durdufi has repeated Filehne's experiment upon animals and has succeeded in producing protrusion of the eyeball by section of the medulla at the level of the auditory nucleus, though he was not able, as Filehne was, to produce goitre and cardiac disturbance.

Hale White has reported the results of an autopsy on a patient who died from pneumonia, after having for years suffered with exophthalmic goitre, in which he found in the floor of the fourth ventricle a number of small hæmorrhagic infarcts. These he attributed to the influence of the circulatory sequelæ of the pulmonary inflammation, upon a place of lowered resistance.

Paul Moebius first put forth the idea that disturbance of thyroid function is the primary stage in the general clinical features of the affection, thus making the disease correlated with myxœdema and cachexia strumipriva. Gautier upholds this theory by citing cases in which surgical operations upon the goitre have caused the disappearance of all symptoms. The study of early cases, however, must negative this view—at least in the eyes of the clinician.

In the matter of therapy, recent contributions do not help us much; although instances of recovery under various methods of treatment continue to be reported. In our own experience, picrotoxin, as recommended by Bartholow, has proved of service.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Fourteenth Annual Meeting, held at Richfield Springs, New York, September 2, 3, and 4, 1890.

The President, Dr. Prince A. Morrow, of New York, called the meeting to order and delivered

THE PRESIDENT'S ADDRESS,

in which he said that those engaged in the practice of dermatology had abundant cause for congratulation. Only a few years ago dermatology had but little standing in America, as shown by the fact that until 1876 only twelve medical schools gave special instruction in diseases of the skin. To-day, as he had learned by the answers to circular letters sent to one hundred colleges, dermatology was a part of the curriculum in eighty-six. But, he said, there is reason to believe that there are many and grave defects in the existing system of instruction, and that the capacity of some of the teachers in our medical schools is doubtful, while the clinical material in the majority of cases is inadequate. Even in large cities the clinical material is too much dispersed. In New York, for instance, instead of having a central hospital for all dermatological cases, as in Paris, the clinical material is scattered in various dispensaries and hospitals.

In the matter of nomenclature, Dr. Morrow said that new names are being introduced into dermatology which are not destined to retain a permanent position, and that while an essentially new disease requires a new name, yet he protested against the present neological craze.

Dr. R. W. Taylor, of New York, then read a paper entitled

OBSERVATIONS ON PRURIGO, CLINICAL AND PATHOLOGICAL.

The author said that new interest in this disease had been excited by Dr. Zeisler's paper, read at the last meeting of the Association, in which twelve cases were described which had been seen by Dr. Zeisler in Chicago. The combined experience of all present at that meeting included only eighteen cases. Dr. Taylor thought that the disease is more common in America than is generally supposed. It is probable that many cases escape recognition and are classed as eczema, scabies, pediculosis, ecthyma, impetigo, and even ichthyosis.

Dr. Taylor then described a case that he had recently seen, and also alluded to the casual concomitants and modifying conditions during the course of the disease. The patient was a healthy girl, nine years old, of healthy American parents in good circumstances, and with healthful surroundings. When four years old she began to scratch, and little red pimples appeared on the face, forearms, and legs, which the parents thought were mosquito-bites. The disease has recurred every year. When first seen by Dr. Taylor, January, 1890, the expression of the child's face was rather dull and her color was the typical white, somewhat ashy hue of prurigo. Over the forehead, temporal region, and cheek was a copious eruption of small conical papules, some whiter than the skin, others of a yellowish hue, and some well capped with a blood-crust the result of scratching. They were not upon the site of sebaceous glands. There was no marked dryness or want of vitality in the hair, although there was slight mealy desquamation in the scalp, such as Hebra describes. The eruption did not appear on the neck and nucha, but began where the shoulder merged into the neck. The principal eruption was on the back of the hand and forearm and on the external and anterior surface of the legs, where the papules were as large as a split pea. There were also some on the arms, buttocks, and thighs. They were scattered and without a semblance of grouping.

Dr. W. T. Corlett, of Cleveland, Ohio, followed with

A CLINICAL STUDY OF PRURITUS HYEMALIS—WINTER-ITCH, FROST-ITCH.

This affection, he said, was first pointed out as a disease by Dr. Duhring, and at about the same time by Mr. Jonathan Hutchinson. In one case in Dr. Corlett's practice it had recurred during the cold season for more than twenty-two years. In another case the eruption had at times the appearance of urticarious patches two

or three inches in diameter, confined to the extremities, subsiding in about ten minutes, and leaving for a short time a dark yellowish spot. A third case was in a negro, showing that that race is not exempt.

The author's experience showed that the state of the general health had no appreciable effect on the pruritus; that the local irritation of the clothing, although capable of aggravating the malady, is not by itself able to produce it; and that meteorological conditions seem to be the main etiological factor. The disease is most common when the temperature and humidity are low, with a wind blowing from the northwest. Under these conditions evaporation is rapid, and the low temperature reduces the glandular activity of the skin to the minimum. As a consequence the skin becomes harsh, the peripheral nerves are irritated, and the disease results. He did not think the primary irritation could be central, else in time it would give rise to a more permanent disease.

The treatment is largely palliative. Internal medication seemed to have little effect in Dr. Corlett's cases, but he had used with advantage an application of ichthyol and resorcin.

DR. E. B. BRONSON, of New York, read a paper on

PRURITUS,

and was followed by DR. J. T. BOWEN, of Boston, who reported a series of cases of

CUTANEOUS TUBERCULOSIS,

and gave the results of his histological studies.

DR. L. A. DUHRING, of Philadelphia, spoke on the

TREATMENT OF DERMATITIS HERPETIFORMIS.

He said that as the several papers published by him on dermatitis herpetiformis contained no reference to treatment, it seemed appropriate to speak now of the treatment of this exceedingly rebellious disease. Each group of cases based on the etiological factors at work require special handling. A speedy cure cannot be expected. It must be remembered that the disease, as a rule, is multiform in character, and that the several varieties require different applications. His experience has been that milder remedies are called for in the erythematous than in the vesicular and bullous forms. A difficulty to contend with is the tendency of the disease to repeat itself, a new crop coming out before the old one disappears. Almost all his cases were chronic, and had previously undergone all manner of treatment.

He has reached the conclusion that the most benefit is derived from stimulating applications, especially those which act as revulsives, such as tar, carbolic acid, sulphur, thymol, ichthyol, resorcin, etc. That which in his hands has proved of the greatest value is sulphur ointment—two drachms of sulphur to the ounce of ointment, applied by thorough and long rubbing, so as to make a positive impression upon the skin, causing, as it were, local shock. Dr. Duhring especially emphasized the manner of making the application. Internal remedies had proven of little avail in most cases.

DR. F. J. SHEPHERD, of Montreal, reported a case of

ATROPHIA MACULOSA ET STRIATA, FOLLOWING TYPHOID FEVER,

and showed photographs of the patient, a boy fifteen years old, who was admitted to the hospital with typhoid fever. During the course of the fever he was delirious, and had epileptic attacks. Macular lines formed, extending across the patellæ and around the anterior aspect of the thighs to near the middle, some being several inches long. They were at first of a reddish color, but became paler, were not distinctly shiny, and were grooved. The interesting point in the case was the occurrence of the atrophic lines in a boy during acute fever.

DR. J. C. WHITE, of Boston, followed with a paper upon

IMMIGRANT DERMATOSES,

in which he said that on a ship the conditions tending to induce skin affections are: homesickness, seasickness, filth, foul air, constipation, inability to take exercise, and contact with others having contagious disease. It is not uncommon for young persons to be attacked, a week or ten days after landing, with an urticarial, bullous, or eczematous eruption. Of imported affections the most common is scabies. The rare affection, melanosis lenticularis progressiva, which Dr. White thought is not seen in native American stock, also occurs. Prurigo also might be regarded as an imported disease, and is scarcely seen elsewhere than in cities with a large foreign population.

The prevalence of vegetable parasitic affections among us is likely to be largely increased by immigration. Tinea favosa, tinea trichophytina, and tinea versicolor are more common in countries from which we receive many immigrants than they are here. The same is true of tubercular affections of the skin, and he is disposed to regard lupus, scrofuloderma, scrofulous gummata, tuberculosis verrucosa, etc., as closely-allied affections, inoculable and auto-inoculable.

In conclusion, the author suggested the propriety of addressing a memorial to the national government with regard to carrying out the following measures: (1) To remove all animal parasites from immigrants on landing, by cleansing the person and clothing. (2) To retain in quarantine all immigrants with contagious skin diseases, including venereal affections. (3) To return to their homes all persons affected with the contagious diseases that cannot be treated in quarantine, such as leprosy, tuberculosis, and advanced syphilis. (4) To provide efficient medical inspection at foreign ports of immigration, with the power to prevent the importation of dangerous diseases to this country.[1]

DR. R. W. TAYLOR then described

A CASE OF SECOND INFECTION WITH SYPHILIS, AND A CASE OF SYPHILITIC INFECTION IN A PERSON HEREDITARILY SYPHILITIC.

The first case was that of a sickly-looking woman, aged thirty-eight years, who entered the Charity Hospital in January, 1890. Eleven years ago she had syphilis, accompanied with a hard swelling of the external genitals, enlargement of the glands, and an eruption entirely over the body. The second year she had rheumatoid pains and mucous patches; the third year, serpiginous syphilides, etc.

[1] Later the Council was given power to carry out this suggestion in a modified form, and to send a memorial to the United States and Canadian governments upon the propriety of these measures.

She married and gave birth to two weak children, which soon died. Her husband dying, she again became a prostitute, and entered the hospital broken-down in health. There were typical miliary syphilides scattered over nearly the entire surface of the skin; all the ganglia were markedly enlarged; there were mucous patches of the tongue and mouth, and evidences of alopecia, and pain in the joints which was worse at night. The second attack was much more severe than the first. She is improving under mercurial treatment.

The second case was one of acquired syphilis in a person hereditarily syphilitic. The woman came to Dr. Taylor in 1879, when she was nineteen years old. At that time he treated her for a destructive syphilitic sore on the face, due to hereditary syphilis, a clear history of which was afterward given by her mother, who acquired syphilis three months before the child's birth. The child had a rash, condylomata cuta, sniffles, etc. In 1885, five years after the patient's first visit, she returned, and then had a roseola, scaling syphilides over the entire body, condylomata of the genitals, mucous patches of the pharynx, etc. The infection began in the right labium, and was contracted from her husband. All the glands were enlarged, and there was alopecia. She has since been cured.

Dr. G. T. Jackson, of New York, then read a paper on

ELECTROLYSIS IN THE TREATMENT OF LUPUS VULGARIS,

in which he said that the advantages of electrolysis, in the treatment of lupus vulgaris, over other and older methods are as follows:

1. It is comparatively painless, and does not require the administration of an anæsthetic.

2. There is not the slightest loss of blood, and thus there is no dread of a surgical operation.

3. The patient is not kept a moment from his occupation, there is no deformity caused by the treatment, and no disfiguring applications are required. He is also spared the discomfort of a swollen face, the ordinary attendant of the arsenical or pyrogallic acid treatment.

4. The treatment goes to the root of the disease with far more exactness and less damage to the surrounding skin than any other caustic or surgical method, and the scar left is smooth and not unsightly.

5. The result obtained is as good as, if not better, than that of any other method of treatment.

Dr. H. W. Stelwagon, of Philadelphia, then showed photographs of

A CASE OF PLICA

which he had seen a few months ago, although he was not sure that plica is the right name for the disease. The woman came to be treated for acne, and called his attention to a lock of hair as thick as one's thumb springing from the middle of the occipital region, closely matted together and falling as low as the ankles, terminating in a brush-like end. It had begun to grow four years before, from no apparent cause; it was not sticky. The rest of the hair fell over the shoulders, and was not matted.

Dr. C. W. Allen, of New York, followed with a paper on

THE TREATMENT OF ERYSIPELAS,

based upon the results of treatment, during the past two years, of 419 cases in the hospitals on Blackwell's Island, not under his care, and 47 cases in his own practice during the same time. Of the former, 21 died; of the latter, 4. Various forms of treatment were employed, and consisted chiefly in applications of different kinds. Dr. Allen thought that, although tending to pursue a definite and usually favorable course, the disease can be checked by treatment. Among the applications used were boric acid, iodine, resorcin, bicarbonate of sodium, ichthyol, collodion, aristol, scarification with the knife, and plaster strips. He is disposed to think favorably of scarification and adhesive plaster, separately or combined, but has tried them in only two cases.

Dr. H. G. Klotz read a paper entitled

NOTES ON PILOCARPINE IN DERMATOLOGY,

in which he reviewed the history of pilocarpine in dermatology, and said that it had not met with the acceptance which one would have expected if its therapeutic virtues were at all proportionate to its diaphoretic qualities. The author has employed the remedy in a few cases, including eczema, pruritus of the anus, and affections with dryness and irritation as symptoms. The results were such as to encourage him to give it a further trial. It can be given internally, or by hypodermic injection, in small doses and continued for a long time. A tenth of a grain is probably sufficient to keep the skin moist.

Dr. C. W. Allen then related his experience with

ARISTOL,

which, he concluded, possesses excellent cicatrizing, granulating, and stimulating qualities, is free from the objectionable odor of iodoform, and seems valuable in certain dermatological cases.

Dr. C. C. Ransom, of Richfield Springs, then reported, by invitation, the

RESULTS OF TREATMENT OF DERMATOLOGICAL CASES BY SULPHUR WATER AT RICHFIELD SPRINGS.

He said that since the new bathing establishment had been completed, 22 cases had been treated, including 9 of eczema, 1 of psoriasis, 4 of seborrhœa, 1 of pruritus, and 2 of urticaria. In nearly all of these cases there was marked improvement, and in some a cure. The temperature of the baths was usually from 95° to 106° F., and they lasted from seven to fifteen minutes. A longer stay in the sulphur bath has a depressing effect which continues for some hours.

The officers elected for the ensuing year are Dr. Greenough, of Boston, President; Dr. F. N. Denslow, of St. Paul, Vice-President; and Dr. G. T. Jackson, of New York, Secretary and Treasurer.

AMERICAN ORTHOPÆDIC ASSOCIATION.

Fourth Annual Meeting, held in Philadelphia, September 16, 17, and 18, 1890.

First Day—Morning Session.

The Association met in the Hall of the College of Physicians, and was called to order by the President, Dr. De Forest Willard, of Philadelphia, at 10 A. M.

After a short business meeting, the President delivered his

ANNUAL ADDRESS.

In a few well-chosen words he welcomed the members of the Association as a Philadelphian, and extended to them the hospitalities of the city.

Referring to orthopædic surgery in Europe, Dr. Willard said that during his trip across the water he had found it in a far less advanced state than he had anticipated. In America it stands farther ahead in its surgical aspect, and in the ingenuity of its mechanical contrivances, than it does across the ocean. Such men, however, as Macewen, Edmund Owen, and Howard Marsh are doing excellent work. He was pleased with Macewen's clear-headed, strong and earnest advocacy of laminectomy and other operations which promise to give relief and assistance in a certain number of cases of caries of the spine with pressure-paralysis.

Following Dr. Willard DR. E. H. BRADFORD, of Boston, read a paper entitled

TREATMENT OF DEFORMITIES OF SPASTIC PARALYSIS,

in which he said that orthopædic surgeons have not done full justice to the surgical treatment of this affection, because the disease has been but little understood, although it is one which occasions distortion and difficulty in locomotion. Light, however, has been thrown upon the subject recently by neurologists, and it is now recognized and studied. The author has not been able to gain permanently satisfactory results by the use of appliances, although in infantile paralysis—sometimes confounded with spastic or cerebral paralysis—appliances are of great assistance. He has not derived any benefit from the use of electricity, and but very little from massage in these cases. Where the lower extremities are affected by this disorder, he has had satisfactory results from tenotomy and myotomy of the resistant muscles,—*i. e.*, the tendo-Achillis, hamstring muscles, and the adductor muscles. After the operation a light appliance should be worn to aid locomotion for a month or so. Permanent benefit may be expected in children free from mental deficiency. His experience included fourteen cases, with ages ranging from four to sixteen years. He had had no experience in operating upon adults suffering from this affection.

DR. ARTHUR J. GILLETTE, of St. Paul, Minnesota, contributed a paper on

TENOTOMY FOR RELIEF OF DEFORMITY IN SPASTIC PARALYSIS,

and reported a case.

The patient was eleven and one-half years of age. The deformity consisted in the flexion of the right forearm upon the arm. Whenever the patient became excited the muscles of the arm became rigid, as did the fingers of the hand of the same arm. The right foot was in the position of talipes equinus, and when the patient attempted to walk so that weight was thrown upon the foot, it was brought into the position of talipes equino-varus.

Dr. Gillette divided the tendo-Achillis, which permitted the foot to come into good position. It also relieved the flexion at the knee. He then placed the foot in plaster-of-Paris and allowed it to remain in this dressing a few weeks, the child playing and walking as much as she desired. When he removed the plaster he applied an ordinary ankle-brace with a "stop-joint" to prevent the foot from returning to its former position. It is now eight months since the operation was done, and the child has not yet had the slightest spasm of any of the muscles of the foot. The ankle-joint will permit of almost all the normal movements, and the patient walks with but a slight limp.

DR. AP MORGAN VANCE, of Louisville, read a paper entitled

AMPUTATION AS AN ORTHOPÆDIC MEASURE.

He said that the introduction of amputation as an orthopædic measure was something out of the recognized lines, but as orthopædists are expected to relieve patients of deformity it is obvious that if amputation in some cases is the best and often the only way this can be done, the operation may be performed by the orthopædic surgeon. In the past ten years quite a number of cases had come under his observation and care in which there was no doubt in his mind that amputation performed for convenience' sake would have been better than any other treatment. Among those in which the knee can be saved will be found a few cases of old infantile paralysis (talipes), and adult cases of congenital talipes, where painful bursæ have developed and life is often unendurable from the pain caused by walking. On the other hand, old subluxated knees with ankylosed patellæ, with flail joints and great shortening, are not uncommon. Some of these cases can be converted from hopeless cripples into useful members of society by a proper amputation and adjustment of a good artificial limb.

Dr. Vance then reported four cases illustrative of the good done by amputation performed for orthopædic purposes.

AFTERNOON SESSION.

DR. HENRY LING TAYLOR, of New York, described

A READY METHOD OF COUNTER-TRACTION AT THE KNEE.

He said experience had shown the obstinate and serious nature of many cases of synovitis and arthritis of the knee, and the frequency of grave sequelæ, unless treated with the utmost care and precision. Properly applied counter-extension with fixation and recumbency usually affords prompt and often marvellous relief to the intense suffering in the active stage of the trouble, and at the same time provides conditions favorable to the proper nutrition of the joint and the subsidence of the inflammatory process. Fixation alone, or simple traction by means of the weight and pulley, however useful in an emergency, give by no means the same results. Dr. Taylor is convinced that the early application of some form of counter-extension is of extreme importance in surgical inflammations of the knee-joint.

DR. F. H. MILLIKEN, of Philadelphia, contributed a paper on the

TREATMENT OF INFANTILE CLUB FOOT PRELIMINARY TO OPERATION.

He offered some suggestions regarding the treatment to be used in cases of club-foot before proceeding with

the operations of tenotomy and osteotomy. Not infrequently we hear of tenotomy, and even of osteotomy, as having been performed on the feet of infants not more than two or three months old. This he considers premature practice.

In private practice and among people possessing a fair amount of intelligence, the traction principle is by far the preferable method of treating infantile club-foot; but in dispensary practice the surgeon meets with a different class.

The directions are not faithfully attended to, and cases show little improvement. For this reason the fixed dressing is preferable for the class of cases that apply for treatment at the dispensary clinic. But neither the fixed dressing nor any other can be depended upon to correct a case of severe club-foot or effect a permanent cure without a final resort to the use of the knife.

Dr. Benjamin Lee, of Philadelphia, in a paper entitled

SACRO-ILIAC DISEASE,

reported two cases, and from them deduced the following corollaries:

1. Disease of the sacro-iliac symphysis induces a characteristic deformity of the spine, of which the features are a lateral displacement of the entire trunk in a direction away from the affected side, a single curve comprising the entire length of the spine, and the almost complete absence of rotation.

2. It also induces a peculiar rolling or waddling gait.

3. It is often the cause of inveterate and excruciating sciatica.

4. It is useless to attempt to remedy the spinal distortion so long as its cause remains unrelieved.

5. The existence of chronic pain in the sciatic nerve, not yielding in a reasonable space of time to medication, should always lead the practitioner to make a careful examination of the spine and of the region of the sacro-iliac juncture.

6. This affection is met with more frequently in adult- than in child-life.

7. Its appropriate treatment consists in splinting the pelvis and thus preventing motion between the opposing surfaces of the symphysis, motion not being its natural function.

8. For the same reason extension cannot be expected to produce the favorable results in this affection that we obtain from it in arthrodial joints.

9. The disease is often of extremely slow development.

10. Its first symptom is often abdominal pain, whence it may readily be mistaken for peritonitis, ovaritis, cystitis, and the like.

11. This pain is principally referred to the side on which the lesion exists.

12. The existence of severe unilateral abdominal pain, accompanied by little or no febrile action, should lead to the suspicion of the existence of this affection.

13. An instrument-maker may, by a happy chance, give temporary relief to a patient suffering from this disease, but as he is entirely ignorant of its seat and nature, he is not perhaps the safest person to refer the patient.

Dr. Royal Whitman, of New York, read, by invitation, a paper on

THE TREATMENT OF PERSISTENT ABDUCTION OF THE FOOT,

in which he said that the successful treatment of any chronic affection demands a personal, persistent attention to details on the part of the surgeon.

The two principal objects in the treatment of this affection are: (1) to overcome the contraction and spasm of the abductors; (2) to straighten the adductors. This is best accomplished as follows:

The patient being etherized, the affected foot is forcibly extended and adducted—that is, both the heel and toes are turned inward so that the inner border of the foot is bent like a bow; it is then forced inward under the leg to a position of extreme equino-varus, the operation being attended with audible cracking of adhesions in all of the diseased articulations. In this position a well-fitting plaster bandage is applied with the object of persistently overstretching the shortened ligaments and contracted muscles and holding the foot firmly in its new position. The bandage may remain on a variable length of time according to the subsequent pain and the difficulty that has been experienced in the reposition. From one to three weeks is the average time for it to remain, after which it may be removed.

(*To be continued.*)

CORRESPONDENCE.

THE MEDICAL EXAMINING BOARD OF VIRGINIA.

To the Editor of The Medical News,

Sir: In connection with a letter appearing in your issue of August 16, 1890, from a correspondent in Seattle, Washington, concerning "Medical Law in the State of Washington," it may be interesting to compare the medical examination as recently held by the State Medical Board of Virginia.

The Virginia Board is composed of thirty-two regular physicians and five homœopathists, and in its *personnel*, in the grade of the questions asked, and in the result of its labors, is excelled by none and equalled by but few, if any, other State boards in the country.

The thirty-seven members composing the board are divided into committees to preside over the examinations upon the following branches: chemistry, anatomy, hygiene, and medical jurisprudence; physiology, materia medica and therapeutics; obstetrics and gynecology; practice of medicine, and lastly, surgery. Six questions are asked upon chemistry, eight upon anatomy, six upon hygiene and medical jurisprudence, eight upon physiology, twelve upon materia medica and therapeutics, twelve upon obstetrics and gynecology, twenty upon practice of medicine, and twenty upon surgery.

The examinations are entirely written, and each applicant is known by a number which is placed opposite his name by the secretary of the board, he being the only member possessing this information. Thus all possibility of prejudice or favoritism influencing the decision of an examination is obviated.

The standard required is a general average of 75 per cent., but a grade of less than 33⅓ per cent. on any one of the subjects examined upon calls for the rejection of the applicant receiving it.

Before the board at its last meeting, on the 3d and 4th of September, 1890, twenty-four applicants for licence to practise in Virginia presented themselves for examination. Of this number, thirteen received the required average, and eleven fell below it, and were, therefore, refused certificates.

The examinations occupied two days, beginning on the morning of each day at nine o'clock and terminating in the evening at eleven o'clock; three hours were devoted to each branch examined upon, and one hour each for dinner and supper was allowed. It will thus be seen that, aside from the mental task, the time required to answer the questions imposed no small physical exertion. The length of time devoted to each branch also conveys some idea of the severity of the examinations.

Your correspondent, who was one of the applicants before the board at its last meeting, went to the examination with the impression that the board was prejudiced against outsiders and against those who are graduates of colleges not situated in Virginia. This impression was received from various sources and your correspondent believes it to be the one generally held in Philadelphia. Never was an impression more falsely founded, and it gives him pleasure to be able to bear testimony to the universal courtesy and fair treatment received from every member of the board before whom he appeared. That so many men, graduates and residents outside of Virginia, have been rejected by this board is due solely to the fact that the applicants have not been fitted to pass an examination before such a body of men as compose the Virginia State Board.

That nearly all the men who are graduates of the Virginia colleges pass these examinations is not on account of any favoritism shown them, but because they are well prepared, in theory at least, to stand the examination. For instance, the University of Virginia requires at its final examination a general average of 83⅓ per cent., a grade certainly not demanded by any college in Philadelphia. The examinations are both written and oral, and your correspondent was assured by a graduate of that institution that its examinations are fair in every particular, and that no cheating is indulged in by the student, a fact of considerable importance in judging of the relative merits of men from different colleges, in some of which, it must unfortunately be admitted, the evil exists to a considerable degree. Of course, such a training as is given its men by the University of Virginia, theoretical though it be, must have its effect in an examination which is in itself necessarily theoretical.

That the Medical Board of Virginia is doing a good work in keeping out of the State men of improper qualifications may be judged by the number of men it yearly rejects, and one cannot but believe that these rejections are just when one hears some of the answers to the questions asked. At the recent examination one of the applicants, who was of course rejected, to the question, "Describe an operation for the radical cure of inguinal hernia," replied that he did not know what hernia was; that it was "one of those new-fangled ideas that had recently cropped up," and that he had not yet heard of it. Another man, a graduate of a Northern college, received a grade of but twenty on chemistry, and one but little higher on anatomy. At the examinations held last year, to the question, "What is a cell, and describe its physiological functions," a brilliant follower of the healing art replied: "A cell is a place of confinement." This answer proved him to be deficient himself in cells—at least of the cerebral gray matter.

Of course this class of men has not been allowed to practise in Virginia, and these facts prove in an unanswerable manner the benefit the Virginia Medical Board is bestowing upon the profession of that State. It also clearly demonstrates the folly and negligence of those States that have not organized examining boards to judge of the qualifications of men desiring to practise medicine within their boundaries. If such poorly equipped men appear before the Virginia State Board, knowing that they will be obliged to stand a rigid examination, what must be the extent of the medical knowledge of some of the men who flock to those States where no State examination is required!

PHILADELPHIA, September, 1890.

ST. LOUIS.

To the Editor of THE MEDICAL NEWS,

SIR: The year 1890 will be a somewhat notable one in the history of medical colleges in St. Louis. Never in this city have there been erected in one year so many buildings expressly for purposes of medical instruction.

I have already mentioned in a previous letter the burning of the Beaumont Medical College building at Clark Ave. and Sixteenth St., and the subsequent purchase of a lot at Jefferson Ave. and Vine St. On this lot the faculty have so far completed the erection of a building that they feel warranted in announcing that the lectures of the regular term will commence there next month, while those of the preliminary course are being delivered in a hall near the college building.

The building is an imposing one in external appearance, and it is well adapted to the special uses for which it is designed.

More ornate and showy architecture is seen in the new building of the Marion Sims Medical College on Grand Ave. and Caroline St., an elevated point in the western part of the city commanding an extensive view in all directions, and affording a fine opportunity for the display of architectural effect which has been utilized to the fullest extent. Whether that elegant residence neighborhood will afford material for extensive clinics, which seem so important an adjunct to college-work, remains to be seen.

Another large and stately building is being erected on the corner of Gamble St. and Jefferson Ave. for the College of Physicians and Surgeons. This is, I think, a much more desirable site than the old one at North Market and Eleventh St.

In addition to these three large and handsome buildings nearly or quite prepared for use this fall, it seems probable that the old St. Louis Medical College is about to join the procession and move westward, for it is stated in the daily papers that the faculty have sold for $75,000 their property on Clark Ave. and Seventh St., which has become very valuable for warehouse purposes on account of its proximity to the railroad and depots, and undesirable as a site for medical college in every respect except for the vast amount of clinical material which is gathered from the densely populated district

surrounding it. Where the College will secure a new location is yet to be decided.

The several medical societies have resumed their stated meetings. The Medico-Chirurgical Society, in accordance with a vote taken last winter, will hold weekly meetings instead of bi-weekly as formerly.

An important practical question for early consideration by this society will be that of location. For the past four years the society has rented a hall in the building of the Post-Graduate School of Medicine, which is centrally located, commodious, accessible, and convenient both as an assembly room and as a library and reading-room. Now that the Post-Graduate School has been absorbed by the Missouri College, it is thought by many that the best interests of the society will not be conserved by having the meetings in the college building, and probably a change of location will be deemed advisable. It would be a consummation devoutly to be wished if the different societies would combine their forces and rent a suitable building, or better yet, erect one, which could be occupied by all, as no two hold their meetings on the same evening. By some such combination of resources it would be practicable to render the libraries of the several societies of much greater practical value to the members, as it would then be entirely feasible to have a paid librarian in constant attendance in the reading-room who could issue books to those desiring to read them at home, and preserve the files of journals.

One reason why comparatively few papers from St. Louis physicians find their way into the medical journals of other cities is that the policy of the St. Louis medical societies has been to make a contract with some home journal by which that journal shall publish all papers and discussions presented or occurring at society meetings. At present the *St. Louis Courier of Medicine* has secured the right to publish papers read before the St. Louis Medical Society, the Medico-Chirurgical Society, and the St. Louis Obstetrical and Gynecological Society.

DOUBLE CEPHALHÆMATOMA.

To the Editor of The Medical News,

Sir: The great interest I felt in the cases reported by Dr. Barton C. Hirst of this rare affection in the newly-born infant, has encouraged me to add two cases from my own practice, which are almost fac-similes of those reported by him.

Last April, I was called to attend Mrs. T., primipara, twenty-two years old. Labor was normal, lasting in its three stages, respectively, nine hours, two hours, and twenty minutes. The child was a male, weighing ten pounds. The head was large, and there was extensive overlapping of the flat bones.

Three days later my attention was called to a small swelling on the left parietal bone. On the following day I noticed a similar swelling on the right parietal bone. In a few days these blood-tumors had reached the size of a hen's egg, the left somewhat larger than the right. Elasticity and fluctuation were distinct, but there was no tenderness on pressure.

I did nothing for these tumors, and when I discontinued my visits to the mother at the end of three weeks they had diminished in size considerably.

Two weeks later, however, I received a note from the mother, asking me to call, as "something was wrong with the bones of the child's head." The tumors had entirely disappeared; but the borders of the parietal bones were rough and raised one-half inch above, and overlapped the occipital bone. I could lay my finger between the bones. Near the posterior fontanelle, from the left parietal projected a piece of bone one-fourth of an inch long, so that the head presented a unique and marked deformity.

As the child was well, I did nothing. He was kept under observation, however, for about three months. At the end of that time his head assumed its normal shape.

In the second case the tumors were on the left parietal bone and on the left side of the occipital bone. Both were small. They subsided in three weeks, without treatment, leaving no deformity.

Frances Hatchette, M.D.

Philadelphia.

THREE PROPOSITIONS TO DR. ERNST.

To the Editor of The Medical News,

Sir: In volume V. of the *Annual of the Universal Medical Sciences*, 1889, Dr. Ernst states that Novy and I, in our little volume on *Ptomaïnes and Leucomaïnes*, make the suggestion that "bacteria may be the products of these alkaloids." In your issue of July 6, 1890, I asked Dr. Ernst to be kind enough to inform me on what page of the volume I could find the "suggestion." Dr. Ernst replied by quoting a part of a sentence, which by being isolated is made to appear to have a wholly different meaning from that which it has in the text, and which has no relation whatever to the question at issue.

Now the difference between Dr. Ernst and myself is easily stated. In the work on ptomaïnes and leucomaïnes, on the first page of the first chapter, I make the following statement concerning the relation between bacteria and ptomaïnes: "Since all putrefaction is due to the action of bacteria, it follows that all ptomaïnes result from the growth of these microörganisms." Dr. Ernst persists in stating that I teach the very opposite doctrine, *i. e.*, that bacteria are produced by ptomaïnes. I have these propositions to make to Dr. Ernst: I will submit the work on ptomaïnes, the article of his in the *Annual*, and our correspondence in The Medical News, to any three teachers of bacteriology in America whom he may mention, and ask them to report over their own signatures whether or not "the suggestion that bacteria may be the products of ptomaïnes" can be found in the little volume written by Novy and myself.

My second proposition is to submit to the same men the question whether or not, in our correspondence in The Medical News of July 5th, Dr. Ernst has fairly and honestly answered the questions which I ask.

My third proposition is to submit to any three scientific men in America, whom Dr. Ernst may select, and ask them to report their answer to The Medical News over their own signatures, the following question: Is it fair and honorable to take from the sentence, "Indeed, so long as the investigation goes no further than this, we are justified in saying that the microörganism may be an accompaniment or consequence of the disease," the clause "we are justified in saying that the microörganism may be an

accompaniment or a consequence of the disease," and print it as an independent sentence, and give it as the meaning of the writer of the complete sentence?

I will ask you, Mr. Editor, to submit this letter to Dr. Ernst, and to inform him that I await his reply.

Respectfully,

V. C. VAUGHAN, M.D.

ANN ARBOR, September 16, 1890

NEWS ITEMS.

A Quack Libel Suit.—Suit has been entered by William Radam, manufacturer of Radam's Microbe-killer, against the *Druggists' Circular*, of New York, for $200,000 damages, the largest amount, so far as heard from, that was ever asked for in a libel suit of this kind.

The pleadings show that the action is brought to recover damages claimed to have been done the business of the plaintiff by an article published in the *Druggists' Circular* for September, 1889. This article gave the result of an analysis of the Microbe-killer made by Dr. R. G. Eccles, a prominent chemist of Brooklyn, who stated that an identical preparation could be made by the following formula:

Oil of vitriol (impure) . . .	4 drachms.
Muriatic acid (impure) . . .	1 drachm.
Red wine, about	1 ounce.
Well or spring water . . .	1 gallon.

This mixture, it was alleged, could be made at a cost of less than five cents per gallon, for which Radam charged three dollars.

It was further alleged that while, when properly used, sulphuric acid, the principal constituent of the Microbe-killer, was a valuable medicine, it was, when taken without due caution or advice, a slow but certain cumulative poison; and the theories advanced by Radam, as to the causes of diseases and the proper method of treatment, were alleged to be totally erroneous. Col. Robert G. Ingersoll, the famous lecturer, is the counsel for the plaintiff.

The *Druggists' Circular*, which is published at 72 William Street, New York, expresses a desire to hear of any case in which unfavorable results have followed the administration of the Microbe-killer, or of any other fact that would be interesting under the circumstances. They claim to have published this analysis without malice and with the sole intention of protecting the public from the loss of their health and money by the use of a dangerous nostrum.

Honors of a Female Medical Student.—Miss Ann Frances Piercy, a student at the London School of Medicine for Women, has gained triple examination honors and two gold medals. In materia medica she held first place, with a medal; in anatomy, second place, with a medal; and in physiology and histology she was first-class.

The Aseptic Hand of the Surgeon.—An aphoristic saying of von Bergmann, on the importance of cleanliness of the hands of the surgeon, has been almost universally quoted by the German journals, as follows: "Infection by contact with the practitioner's hands plays no inconsiderable part in the etiology of the diseases of wounds, and the much-prized skilled hand of the surgeon may bring the greatest harm with the tenderest touch."

An Association of Medical Legislators.—The medical members of the French parliament have united to form an association for the purpose of taking concerted action upon proposed laws regulating the medical profession and the sale of medicines. The profession is more largely represented than before, in recent years, upward of eighty being physicians.

Accidental Poisoning in Bellevue Hospital.—In the case of a typhoid-fever patient who recently died from an overdose of carbolic acid in Bellevue Hospital, New York, the coroner's jury censured the nurse for his carelessness in administering strong acid when dilute acid had been ordered. The jury further found that the "said negligence was, in part, attributable to the authorities of Bellevue Hospital, who neglected to label properly the medicine prescribed by the regular physician, and who allowed made-up prescriptions for internal use to be mingled in the same chest with poisons of a violent nature, intended for external use only, and the whole to be placed in the control and custody of inexperienced nurse pupils, and in this case of one below the average intelligence."

Rhinoplasty in India.—A notable literary and scientific production, from the native press of Junagadh, India, is a description of one hundred cases of rhinoplasty, by Surgeon Trilovandas Motichand Shah, chief medical officer at the Junagadh Hospital. The author has collected the cases within four years, under peculiar circumstances. The deformities for which this procedure was required were not the results of disease, but of wilful mutilation committed either in revenge or as a causeless outrage on innocent persons, by a class of miscreants known in that country as the Makrani outlaws. The book is illustrated by photographs, which clearly show the extent to which the facial mutilation is carried by these criminals, as well as the signal improvement effected by surgical treatment. The author, who has worked upon his subject with much zeal and success, strongly advocates the old operation, in which the flap is taken from the forehead. It requires less time than the cheek-flap operation, and the subsequent disfigurement is much less, the forehead scar being readily concealed by the turban almost universally worn by the people of the province where these mutilations chiefly occur.

An Epidemic of Beri-beri.—A whaling bark has arrived at New Bedford, Massachusetts, after a cruise of five years. While off the coast of Patagonia several months ago the seamen were attacked with what is believed was beri-beri. Thirty-four of the crew of thirty-seven were ill with the disease at one time, and nine cases proved fatal.

Burns from Chlorate of Potassium.—According to the *St. Louis Medical and Surgical Journal*, workers in chlorate of potassium manufactories have their clothes so completely saturated with the salt that recently one of them was severely burned by striking a match on his trousers. His clothes were at once a mass of flames,

and, although immediately plunged into a pool of water, it is probable that the burns will be fatal.

Medical Work in the Cholera Districts.—It is stated that the physicians at work in the cholera-infected districts of Spain continue to be ill-used by the peasants, who are opposed to the enforcement of precautionary measures. Notwithstanding that the physicians are provided with a military escort, three have been killed by the peasantry.

Leprosy in Surinam.—The Bishop of Dutch Guiana, who was recently in Baltimore, made an appeal for the lepers in his diocese. The disease has been unchecked by any sanitary precautions of the government, and has spread to a serious extent in Surinam. Three priests who came in contact with the diseased have become leprous, and one of them is now paralytic and helpless. This heroic priest, like the late Father Damien, of Malakao, left his home to spend his life among the neglected lepers of a foreign land. He first noticed the signs of the disease in himself in 1880.

A Prelate's Charity.—Cardinal Manning, not long since, was presented by his friends with an illuminated address and a purse of $37,000, in token of the silver anniversary of his episcopacy, and he soon afterward made public his intention to devote a large portion of the money-gift to the endowment of a bed in the accident ward of the London Hospital, for the use, *in perpetuo*, of humble workingmen who may be injured on or along the River Thames.

The Montreal General Hospital.—This conservative and venerable institution has turned over a new leaf, and, according to the *Montreal Medical Journal*, has never before been in so good a condition, The house staff are uniformed in white patrol-jackets, while the trained nurses are dressed in pink and white, with caps and badges. The wards look fresher and more business-like. The out-patient department has been enlarged, and fitted for the accommodation of the specialists. Clinical instruction will be better provided for than in the past. "The venerable institution has merely been drowsy, and is not yet moribund."

Obituary.—Dr. Phanuel Euclid Bishop, of Pawtucket, R. I., died of Bright's disease, September 21st, at the age of forty-six years. The deceased entered Brown University in 1862, but at the end of one year enlisted in the Union army. Soon rising to the rank of Second Lieutenant he was sent to New Orleans, and was for a time stationed at Fort Jackson. He was subsequently made Captain, was detailed as judge-advocate on court-martials, and was provost-marshal of St. Mary's parish in New Orleans. After the war he went West and graduated from a business college in Chicago, was superintendent of schools in a city of Iowa, and travelled considerably. Returning to Pawtucket, he was connected with the public schools for some time as teacher, and then as superintendent. At this time the degree of Master of Arts was conferred upon him by Brown University. Meanwhile he had found time to study medicine and attend lectures at Bowdoin and Dartmouth medical schools. He practised successfully in Pawtucket for seventeen years. He was a Fellow of the Rhode Island Medical Society, a Mason, an Odd Fellow, and a Forester. Two children and an only sister survive him.

—— Dr. Josef von Jelenffy, an eminent laryngologist of Hungary, did not return home alive from the Berlin Congress. He was able to attend the meetings of one day only, when he was prostrated by cardiac disease and was taken to the Catholic Hospital. He died soon after. At his funeral, which was attended by all the members of the laryngological section then remaining at Berlin, Dr. B. Fränkel, president of that section, delivered an address commemorative of the life and services of the deceased, speaking of him in most sympathetic terms.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 15 TO SEPTEMBER 22, 1890.

Middleton, Johnson V. D., *Major and Surgeon.*—Is relieved from duty at David's Island, N. Y., and will report in person to the commanding officer Fort Columbus, New York City, for duty at that station, relieving Joseph Gibson, Major and Surgeon, and reporting by letter to the commanding general Division of the Atlantic. Major Gibson, on being relieved by Major Middleton, will report in person to the commanding officer David's Island, N. Y., for duty at that station, and by letter to the Superintendent of the Recruiting Service.—Par. 1, *S. O. 219, A. G. O., Washington*, September 18, 1890.

By direction of the Acting Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered:

Spencer, William G., *Captain and Assistant Surgeon*, will, upon the abandonment of Fort Bridger, Wyoming (his present station), report in person to the commanding officer of Fort Omaha, Nebraska, for duty at that station, relieving Alfred E. Bradley, First Lieutenant and Assistant Surgeon. Lieutenant Bradley, on being relieved by Captain Spencer, will report in person to the commanding general Department of the Platte, for duty as Attending Surgeon at the Headquarters of that Department.—Par. 16, *S. O. 214, A. G. O., Washington, D. C.*, September 12, 1890.

By direction of the Acting Secretary of War, leave of absence granted William N. Suter, *First Lieutenant and Assistant Surgeon*, in Special Orders No. 149, June 26, 1890, from this office, is extended fourteen days.—Par. 6, *S. O. 214, A. G. O., Washington, D. C.*, September 12, 1890.

By direction of the Acting Secretary of War, the leave of absence for seven days, heretofore granted Henry McElderry, *Major and Surgeon*, by the Superintendent of the U. S. Military Academy, is extended to November 10, 1890, on account of sickness.—Par. 5, *S. O. 214, A. G. O., Washington, D. C.*, September 12, 1890.

By direction of the Acting Secretary of War, John J. Cochran, *Captain and Assistant Surgeon*, now on duty at Fort Adams, R. I., will proceed to Mount Vernon Barracks, Ala., and report in person to the commanding officer of that post for temporary duty, and, on completion of the duty contemplated, he will return to his proper station.—Par. 2, *S. O. 214, A. G. O., Washington, D. C.*, September 12, 1890.

By direction of the Acting Secretary of War, leave of absence for three months, commencing about October 1, 1890 is granted Frank J. Ives, *Captain and Assistant Surgeon*, provided one of the Assistant Surgeons serving in the Department of the Missouri can be assigned to duty in his stead at Fort Sill, Oklahoma Territory, during that time.—Par. 26, *S. O. 213, A. G. O., Washington, D. C.*, September 11, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 20, 1890.

Olcott, F. W., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Alert."

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, OCTOBER 4, 1890. NO. 14.

ORIGINAL ARTICLES.

THREE TYPES OF CEREBRAL SYPHILIS PRODUCING MENTAL DISEASE.

BY C. M. HAY, M.D.,

ASSISTANT PHYSICIAN AND PATHOLOGIST TO THE STATE ASYLUM FOR THE INSANE, MORRIS PLAINS, NEW JERSEY.

THE effects of the syphilitic poison upon the brain are so variously expressed that it is important to remember that mental disease is, at times, produced by syphilis without any physical symptoms being present to aid us in diagnosis. This is now a too well-authenticated fact to need particular emphasis. That syphilis is frequently overlooked, however, in cases of beginning insanity there is much reason to believe, and I will cite a case in which only the accidental discovery of the fact that the man had previously contracted syphilis led to correct therapeusis. In certain rare cases of simple mental disorder following syphilis there is no local pain, convulsions, or significant cranial-nerve spasms or paralyses to indicate the presence of a gross lesion, and a clear specific history or the therapeutic test alone will indicate the real cause.

Commonly, however, the proofs of the existence of organic lesions of the brain or its membranes are not wanting, and a cranial-nerve palsy or spasm, a convulsive seizure, a sudden or gradual attack of hemiplegia, or violent local head-pain, with, perhaps, other neuralgic symptoms, will make us suspect that syphilis is the true cause of the patient's mental disorder. It is generally said that any form of mental disease may be the result of syphilis, and yet the *rôle* that the latter plays, particularly in the production of general paralysis of the insane, has been, and is to-day, still wholly unsettled, some authors rating it as a very prominent, and others as a comparatively insignificant, cause of that affection. That syphilis can produce a form of general paralysis which is curable is admitted by many. In connection with this, Professor H. C. Wood[1] writes:

"In conclusion, I may state that it must be recognized as at present proved that syphilis may produce a disorder the symptoms and lesions of which do not differ from those of general paralysis; that true general paralysis is very frequent in the syphilitic; that the only constant difference between the two diseases is as to curability; that the curable sclerosis may change into or be followed by the incurable form of the disease."

[1] Nervous Diseases and their Diagnosis, p. 495.

This view is also held by Griesenger, Mendel, Foville, Esmarch, Legardelle, Lamet, Rollet, and many other prominent clinicians. Another school maintains that the encephalopathies produced by syphilis are distinguishable from true general paralysis.

Therefore, although the question cannot be considered to be settled, still, in reading over the literature of this subject, it would seem that the burden of proof rests with those who, with Professor Wood, consider the syphilitic form indistinguishable from true general paralysis. Assuming this to be the case, the recognition of the presence of syphilis is, in all incipient cases of general paralysis of the insane, very important, and in all doubtful cases specific treatment should be adopted as the therapeutic test between the two forms of the disease.

Syphilis is, however, so constantly thought of in connection with general paresis that probably it very rarely escapes recognition, and I believe it is in the case of less marked psychoses that it is more likely to be overlooked as an etiological factor. The frequent inability to get a true history of the case and the remote period at which symptoms may occur are additional reasons for very careful exclusion of the syphilitic diathesis in all cases of obscure origin. In some cases that I have seen during the past two years the recognition of syphilis as the true cause of the mental disease has resulted in a complete cure of the patients, who, otherwise, were undoubtedly doomed to hopeless dementia; and the impressions received from the observation of those cases form the subject of this paper. It would seem, therefore, that the point cannot be too strongly insisted upon that, when rather atypical mental symptoms appear in a subject over twenty-five years of age, the presence or absence of syphilis should, if possible, be determined, especially when other apparent causes are wholly wanting, and that the therapeutic test should be applied, if syphilis cannot be otherwise excluded. No harm can be done to the patient by its careful application, and, if syphilis should be present, there will be, in the majority of cases, the most gratifying amelioration of all the symptoms, and perfect cures are by no means rare.

In the cases of syphilitic brain-disease that have come under observation in the New Jersey State Asylum a comparatively large proportion have exhibited a progressive dementia. In two cases this

was very marked, and closely resembled an attack of that rare mental disease, primary dementia. There did not appear to be anything in the condition of these two cases to distinguish them from primary dementia. So that while differential points may be entirely wanting between certain cases of syphilitic psychosis and acute primary dementia, in the former there will usually be the history of syphilitic infection and the absence of any obvious exciting cause, such as sudden grief, fright, remorse, or exhausting illness. The different periods of life in which these two affections occur will also guide us; for, while primary dementia usually occurs before the age of twenty-five years, syphilitic mental disease is far more common after that age. Sex, also, should be considered, males being more subject to syphilis, while sex exerts little influence in the causation of primary dementia. These distinctions are by no means fixed, and the diagnosis between the two conditions must at times be difficult. Still, the above considerations usually furnish valuable hints as to the probable diagnosis, and combined with the therapeutic test they furnish a fairly adequate line of reasoning.

The following cases are taken almost at random from my notes, but they may serve to illustrate some types of syphilitic mental disease, other than general paralysis of the insane, which, I have reason to believe, are of quite frequent occurrence:

Case I.—Mr. R., aged forty years; married; native of New Jersey. Admitted, April 15, 1890. No hereditary predisposition to nervous or mental disease. No history of syphilis could be obtained on admission. His attack had commenced two months before with melancholia and a "numb feeling" in the head.

At the time of his admission his physical condition was good, and no local disease could be discovered. His mental condition was one of listless apathy; he would sit for hours with a perfectly expressionless face; he answered questions slowly and aimlessly, and appeared to take very little interest in his surroundings. He failed to comprehend conversation well, his replies being at times irrelevant and meaningless. After being aroused by a question he would immediately relapse into silence, with the same dull, vacant stare, and the eyes looking straight forward. It was learned that he had had an attack of "grippe" some time previously, and that at two periods—six and two years ago, respectively—he had had slight attacks of melancholy, which were attributed to some domestic trouble.[1]

For two months succeeding his admission he grew worse, dementia became more marked, and the probable diagnosis of primary dementia was made, when by accident it was discovered that the man had acquired syphilis. He was at once given potassium iodide, commencing with 30 grains three times daily and rapidly increasing the dose until 1 drachm three times daily was taken. He was kept upon these doses for a time, but at present he is taking 15 grains three times daily. The effects of this treatment were marked, and the improvement in the mental condition could be noted from day to day. Memory came back slowly, but surely; the face took on expression, and reasoning and judgment returned. He began to converse freely and intelligently, and the "slightly dead or numb feeling" in the head coincidently disappeared. To-day he considers himself in about his usual health, but he will continue to take the iodide for some time to come. In this case the mental disease corresponded exactly to some cases of primary dementia which have occurred here.

The next case exemplifies a more frequent type. In the preceding case a peculiar, drowsy dementia, with slight "numb feeling" in the head, were the only symptoms; but the class of patients of which the following is an example give a history of sudden or gradual hemiplegia, with or without aphasia, and if not preceded, usually followed, by convulsive phenomena. To what extent the mental symptoms are due to direct irritation from gross lesions, or, on the other hand, to a direct action of the syphilitic virus on the brain cortex, can only be conjectured, and it is of no practical importance to determine, for, with our present knowledge of the subject, there can be but one rational treatment for such cases.

Case II.—Mr. S., aged thirty-one years; married: has no children; native of New Jersey; fairly educated, and a clerk by occupation.

Admitted, April 15, 1889, with the following letter from his physician: "Patient underwent treatment for primary syphilis about four years ago. One year ago he had a stroke of paralysis during the night, after a hard day's work, and since then has shown, at times, signs of mental derangement. The power of speech has not been good since then, and there is a tendency to cry and to be forgetful, and, of late, mental confusion and an inclination to wander away from home. He has also threatened suicide."

Examination on admission showed the following conditions: Medium-sized man, of light complexion, with pale, relaxed features and soft, flabby muscles. The left pupil was slightly smaller than the right. Field of vision, ocular movements, accommodation, and color-sense good. There was difficulty in speech, the pronunciation being jerky, uncertain, and irregular. The tongue protruded nearly straight, but was tremulous and clumsy in movement. There was inability to select proper words quickly, but if time were given the patient he could usually complete his thought. The right arm and leg showed marked incoördination of movement and a slight paresis of this side when compared with the left side of the body. A pin was picked from the floor awkwardly, and his writing

[1] Since the recovery of the patient he has informed me that those attacks were due to the knowledge that he was the victim of syphilis contracted eight years before his admission here.

was almost illegible, but the spelling was correct. The patellar-reflex was highly increased on the right side and slightly so on the left side. The sensations of pain, heat, and cold seemed normal.

The mental condition was one of melancholia mingled with a considerable degree of dementia. Memory was lost for recent events and much impaired for remote ones. He seemed to be in a hopeless, dazed, emotional state, with, at times, mental hebetude approaching complete dementia. He could, however, be readily roused into conversation, which he would, sometimes, carry on in a fairly intelligent manner. For several months prior to admission he had been wholly unfit for business, and frequently wandered off to distant cities, where he would be found, unable to explain his curious conduct. He had no delusions.

He was immediately given 30 grains of potassium iodide with $\frac{1}{24}$ grain of bichloride of mercury three times daily. During the first two months of treatment he showed little improvement, and had four convulsive seizures, affecting the right side of the body. After these seizures the aphasia and the incoördination and paresis of muscles were decidedly worse. The convulsions were ordinary epileptiform attacks, and were attended by no further eye-symptoms than those already noted. After this period the convulsions did not recur, and rapid improvement began. The mind cleared, speech became easy and natural, and the incoördination and paresis almost wholly disappeared from the right arm and leg. He remained under treatment three months after he considered himself fit for business, and was discharged, practically cured, December 14, 1889. I have since frequently heard from him, and he is still well and attending to business, having had no return of his mental or physical troubles. At his discharge he weighed thirty pounds more than on admission, his muscles were hard and complexion ruddy, notwithstanding the large doses of the iodide. The mercurial was omitted from the treatment after four months, when decided improvement had begun, and the potassium iodide was increased until, at one time, he was taking 200 grains daily. Regular out door exercise constituted an important element in treatment while the patient's mind was returning to its normal condition. At no time did symptoms of salivation or iodism appear.

The case just detailed is instructive in showing the good effects of long-continued large doses of anti-syphilitic remedies in such cases. Had the treatment been abandoned as useless after the first two months, during which time convulsions and no perceptible improvement gave a hopeless aspect to the case, it is only fair to presume that the patient would have gone rapidly downward, and that a long terminal dementia, or death from exhaustion or in a fit, would have been the end. Hence, persistent treatment should be adhered to for months, even if improvement does not occur.

The last case that I will describe is one of a class having very definite symptoms of organic lesions, which usually appear gradually, and may be preceded, accompanied, or followed by mental disease. The case also illustrates the remarkable improvement which will sometimes follow huge doses of specific remedies under apparently desperate circumstances. Another important lesson taught by this case is that death is frequently due to neglect of treatment, which, in the present instance, afforded us an autopsy. There is no doubt that a final recovery would have occurred in this case also, had his medicine been continued for a sufficient length of time. The failure to carry out treatment is a frequent cause of relapse in such cases, and patients cannot be too emphatically told of the risks they run in neglecting to follow a long course of treatment after all active symptoms have passed away.

Case III.—Mr. C. Y., aged thirty-nine years; native of New Jersey; a plumber by occupation, and with no trace of mental or nervous disease in his family history. His previous diseases were only those incident to childhood and youth. He contracted syphilis at about the age of thirty-four years.

Thirteen months before admission he began to show mental symptoms consisting of causeless melancholy, unstable temper, with emotional periods, when he would cry over some imagined woe. He became restless, roamed about the town, and worked only fitfully at his trade. He was utterly disheartened, especially in the mornings. With these symptoms, memory rapidly failed, and at his admission to the asylum, November 5, 1888, it was almost entirely gone. He also lost in weight. On June 7, 1888, he had a slight stroke of paralysis, affecting the right side, and after this, mental deterioration was more rapid. He imagined that his mother was dead, and various other delusions also occurred at this time.

For the following notes of his condition, shortly after his admission, I am indebted to my friend, Dr. L. L. Mial, under whose care the patient was, until December 1, 1888, when I first saw the case. Dr. Mial informs me that, beginning with violent pain in the left frontal region, there was progressive paralysis, occurring as follows: Partial ptosis of left eyelid, gradually becoming complete, accompanied with external strabismus and, later, with dilatation of the pupil of the same eye; then paresis, deepening into paralysis, of the left arm, and after the arm, the left leg became similarly affected. Sight remained good. Sensation was normal. The face and tongue were unaffected. His speech-memory was absent. Dr. Mial placed the patient on the mixed treatment, and by the time he came under my care, December 1, 1888, he had nearly recovered from his paralysis, and intellection was fairly good. The treatment was continued, and two months later he passed from observation, nearly cured mentally and physically.

Through neglect he did not continue to take the remedies prescribed, and he returned, March 1, 1889, with extensive paralysis, which had com-

menced a few days previously. First, the left arm became "numb," and memory completely failed; on the following day the left arm was completely paralyzed, and the left leg was "very cold," while, at the same time, the right arm showed decided weakness. On the third day the bladder was paralyzed and the right arm was flaccid, and the day following the development of these symptoms the right leg was paretic. On March 7, 1889, the man was almost completely paralyzed, the only exceptions being the face and tongue, and the right leg, which could be very feebly moved. Elsewhere the paralysis was perfect and complete. Rapid emaciation had occurred prior to the paralysis, and on admission he was in a very feeble condition. He was placed upon general tonics, with stimulants and potassium iodide 40 grains, with biniodide of mercury $\frac{1}{20}$ grain, three times daily.

March 11. Right hand can be feebly extended. Urine drawn. Iodide increased to 50 grains three times daily. Areas of anæsthesia were noted over chest and abdomen and left extremities.

16th. Moves right arm, hand, and leg slightly, and slight voluntary movements of left hand can be performed. Left leg still completely paralyzed. Pupils nearly equal in size, but the right is slightly more dilated than the left; both react to light. Temperature, 99°–102½°. Pulse weak, 100, and occasionally drops a beat. Urine acid; specific gravity 1020; no albumin or casts; contains excess of phosphates.

19th. Power in right side increased. Left arm can be raised from the bed, but movements of the wrist or fingers are not performed. Mental condition is one of stupor, from which he can be easily roused and made to answer questions intelligently. Memory totally gone; cannot remember my name longer than two or three seconds. Biniodide of mercury omitted from treatment. Tongue, heavily coated, is protruded well, and does not deviate. Fever continues. Sight remains unaffected.

31st. The same amount of fever and paralysis.

April 4. Muscular power is fairly good on right side, and there has been decided gain in left arm. Wrist- and finger-movements are now feebly performed. Pupils equal and of about the normal size. Bedsores forming.

18th. No change in paralysis. Abscess of right thigh evacuated of about a pint of apparently gummatous pus. Extensive bedsores. Patient failing.

25th. Patient died to-day, from exhaustion.

Autopsy: Calvarium very thin and brittle, diploë diminished. Dura abnormally adherent to the bone. A slight excess of cerebro-spinal fluid. No marked atrophy of brain, and no gross lesion of the cortex. Weight of brain, 41 ounces. In the left hemisphere, and involving the anterior third of the optic thalamus, was an area of bright reddish-yellow pigmentation surrounding a dark centre, the whole being nearly the size of a silver dollar. The dark centre, the size of a five cent piece, was situated in the anterior end of the optic thalamus, and consisted of broken-down brain-substance infiltrated with blood, and, under the microscope, disorganized brain-tissue, blood-coloring matter in masses, and the products of fatty metamorphosis were seen. In the left crus, just above and including the point of exit of the third nerve, was a patch of similar color, but without any broken-down area, the deep pigmentation being the only macroscopic appearance. Microscopically, abundance of pigment-granules, with numerous round-cells infiltrating the area, were seen. The nerve-fibres appeared to be separated in places by aggregations of these cells. No notable destruction of the fibres was detected.

In the right hemisphere, just beneath the floor of the lateral ventricle and between the optic thalamus and the caudate nucleus, was an abscess, three-quarters of an inch antero-posteriorly and half an inch in width. This involved the anterior extremity of the optic thalamus only to the extent of a line, and was thus situated somewhat more anteriorly than the lesion on the left side. It involved the fibres of the anterior segment of the internal capsule from the knee forward for a distance of three-quarters of an inch. The abscess was about three eighths of an inch deep. Surrounding it was an area of red softening about three lines wide, and outside of this zone was another of bright reddish-yellow pigmentation exactly similar to the condition found in the left hemisphere. Microscopically, the contents of the abscess were found to consist of compound granule-cells, broken-down nerve-tissue, pigment-granules, and granular débris, with cells resembling ordinary pus-corpuscles.

With the exception of increased adherence to the bones of the skull and a little thickening along the vertex, the dura was normal.

The arachnoid was generally slightly opaque. The pia was not adherent to the brain-substance anywhere and presented only increased vascularity. The brain-substance, and particularly the cortex,[1] were congested. No other gross lesions were discovered in the brain-substance.

The vessels showed marked thickening of the internal coat, and the left, middle, and anterior cerebral arteries were especially affected. In places the calibre of the vessels was notably diminished.

The post-mortem changes found in this case would seem to explain fully the paralytic symptoms that existed during life. The remains of the lesion of the left crus, revealed at the autopsy only by deep pigmentation and the results of what apparently had been an inflammatory condition, probably originated from the extensive disease of the vessels—syphilitic endarteritis. The three lesions found seemed exactly similar in nature and differed only in degree. The one in the right hemisphere was the most destructive, producing an abscess; the one in the left hemisphere was of less serious consequence to the brain-substance, a small necrotic area in the anterior part of the optic thalamus being its result, while the appearances around both of these lesions were identical and corresponded exactly to

[1] Microscopical examination of the cortex has not yet been completed, but will probably appear in the next annual Pathological Report of the New Jersey State Asylum for the Insane.

the area of the left crus which has been described. Whatever the process of formation of these lesions—and the appearances certainly strongly indicate the presence of at least a reactive inflammatory process—there can be little doubt that the attack of ocular paralysis on the left side, with left brachial monoplegia, was due to the lesion in the crus, with, of course, the possibility that at the same time the lesion in the right hemisphere also participated in the causation of the left-arm paralysis. The prompt treatment which the patient underwent at that time apparently had the effect of so modifying the crus-lesion that nerve-conduction was restored, as was shown by the disappearance of the paralytic symptoms and the patient's recovery at that time. The nearly symmetrically situated lesions of the hemispheres sufficiently explain his last and fatal attack and the bilateral paralysis. While the left arm regained a little motion, the left leg remained completely paralyzed until death; this is interesting in view of the more extensive lesion of the right internal capsule, half the diameter of which must have been included in the abscess-cavity. That the right side recovered power is only what would be expected in looking at the lesion of the left side, which scarcely interfered with the internal capsule, except by a zone of pigmentation.

The local severe frontal pain, complained of during his first attack, in November, 1888, is not explained by the post-mortem examination. Reasoning from the appearance of the lesion in the right hemisphere, and from the crus-lesion, which was evidently older, I am inclined to the belief that the latter was mainly responsible for the symptoms occurring in November, 1888, and that the two other lesions were coincidently developed, the right one being more extensive and serious in its effects upon the brain. Taking into consideration the extensive arterial lesions present, it does not seem unlikely that the primary pathological process was thrombosis, with secondary reactive inflammation and softening. This view is somewhat supported by the symmetry of the lesions.

These three cases, I think, are pretty fairly illustrative of the types of syphilitic brain-disease combined with mental disease to which I have referred. Other syphilitic manifestations, of course, occur in conjunction with insanity, and I have selected these three types only because common ones, and also because they illustrate the good effects of early and persistent anti-syphilitic treatment. The class of cases illustrated by Case I., and, to a less degree, by Case II., would seem the most important from the standpoint of diagnosis, for early treatment is all-important as regards the cure of the patient. In many cases sudden hemiplegia is the first symptom noticed by the patient, and when this occurs in a comparatively young man there is reason for suspicion.

The practical conclusions suggested by the observation of these cases are as follows:

1. That primary mental disorder following syphilis can often be completely relieved by energetic anti-syphilitic treatment.

2. That it is of vital importance that the patient continue under treatment for not less than one year after active symptoms have ceased.

3. That in some cases of bilateral paralysis the cause is bilateral syphilitic lesions of the internal capsules.

INCREASE OF HYPEROPIC ASTIGMATISM.

By EDWARD JACKSON, M.D.,
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

There is little reason to doubt that, as is commonly believed, in the great majority of eyes the amount of astigmatism remains the same throughout life. That in progressive myopia, changes in the shape of the eyeball should to some extent involve the cornea, and so cause changes in the amount or direction of the astigmatism, was rather to be expected, and the expectation has been justified by reported cases. At one of the early meetings of the American Ophthalmological Society Dr. O. D. Pomeroy described the case of an artist who seemed to have acquired a myopic astigmatism from straining his eyes at portrait-painting.

Increase of hyperopic astigmatism is, however, a different matter. Here we are not led to expect the changes in the shape of the globe that attend the increase of myopia; although cases reported by Risley and Norris show that diminishing hyperopia may be essentially the same morbid process as increasing myopia.

In 1885 Dr. S. Theobald reported to the Ophthalmological Society three cases of astigmatism markedly increased after intervals of some years, of which one was hyperopic. And although the latter case was that of a young man whose eyes had not been submitted to the influence of a mydriatic at each examination, it is probably a case of the kind now under consideration. Two years ago Dr. J. B. Emerson reported to the Society a very striking case of this kind; and at the recent meeting of the American Medical Association Dr. O. B. Frothingham reported a similar case.

My attention was drawn to the subject by the increase of three-fourths of a dioptre in my own compound hyperopic astigmatism. I have since noted seventeen cases which are elsewhere detailed, being all the cases that I have met with in private practice in which the change of astigmatism in either eye

[1] The substance of a paper read before the American Ophthalmological Society, July 17, 1890.

amounted to 0.5 D. or over, the refraction having in each instance been carefully and repeatedly measured under full mydriasis.

In all of these cases the balance and strength of the ocular muscles were carefully and repeatedly tested. In several of them no tendency toward deviation of the visual axes was discovered; in most of the others apparent tendencies of this kind disappeared under the constant wearing of correcting lenses for the anomaly of refraction. In only one was there a marked, persistent tendency of this kind —esophoria. My observations, therefore, do not indicate any special relation between defects of the extra-ocular muscles and increase of astigmatism.

It would be very interesting to know something of the frequency of these cases relatively to the whole population, but my series of seventeen cases throws no positive light on the subject. One cannot estimate what proportion of his patients would return to him should there be a recurrence of their asthenopia, or other symptoms, after the lapse of four and a half years, the average interval in these cases. I have on my records a large number of cases that came to me from competent colleagues with glasses that did not correct the hyperopic astigmatism that their eyes presented. And, doubtless, my colleagues have on their books cases coming from me in a similar condition. Then there are, probably, many in whom the change of 0.5 D. in the astigmatism of one or even of both eyes has not led to a recurrence of asthenopia or other annoyance, for there are many in the community who do not have trouble from that amount of original error of refraction.

Should I hazard a guess at the frequency of these cases of progressive hyperopic astigmatism, it would be that they constitute about two per cent. of all cases seeking relief on account of anomalies of refraction. The cases in which, after the lapse of an equal length of time, the use of a mydriatic has shown me no change in the amount of astigmatism, outnumber them very decidedly; and cases of mixed and myopic astigmatism are relatively, not absolutely, more frequently progressive.

It is of interest to note that no case of regressive astigmatism was encountered, none in which the astigmatism diminished so much as half a dioptre. But it is not improbable that such cases do occur.

It seems probable that progression of astigmatism is determined in some cases by the chronic congestive and inflammatory conditions allied to those of progressive myopia; but acting rather on the anterior segment of the eyeball, and determining a change in the shape of the cornea. But, while the change in the shape of the cornea may thus be caused by distention, the normal gradual increase of hyperopia, which Priestley Smith has shown to be due to the gradual increase in the size of the crystalline lens, would cause the change in refraction to be, chiefly, in the direction of increased hyperopia in all meridians, as was observed in most of my cases.

In many of the cases there is a clear history of renewed symptoms of congestion or chronic inflammation, coincident with the change in the amount of astigmatism, quite similar to those which occur in progressive myopia; and in six of the cases there was actual diminution of the hyperopia in one principal meridian of one or both eyes. The condition of impaired nutrition in the ocular coats might be part of some general impairment of nutrition, though none of the cases is noted as giving a clear history of such general ill-health (a history very frequently obtainable in conical cornea): or it may arise from eye-strain due to unusual exertion of the eyes, of which there was a clear history in several cases, or from uncorrected hyperopia due to the normal increase of the lens.

On the other hand, it is likely that in some of these cases the increase in astigmatism is directly due to an unsymmetrical increase in the bulk of the lens, causing more rapid increase of the hyperopia in some meridians than in others. The binocular symmetry of the increase, in certain cases, points toward an individual developmental tendency; while the blood-relationship between some of the patients seems to indicate a family tendency in others. Thus, two of the patients were brothers, two were sisters, and two were first cousins, and in each pair of relatives the astigmatism was progressive at about the same period of life, and in about the same meridians.

From this series of cases we must conclude that liability to change in the amount of astigmatism is not confined to any particular period of life, though such changes are more frequent in early life. My study of the subject leads me to these conclusions:

1. Astigmatism is by no means constant in degree, though decided changes are exceptional.

2. Changes in its amount, and slight changes in the direction of its principal meridians must be looked for. These changes are not due to muscular defects nor confined to any particular period of life.

3. When a patient comes with lenses prescribed some time previously by a colleague, and which do not now correct the ametropia, we must not jump at the conclusion that these lenses were inappropriate at the time they were ordered.

A CASE OF EXTRA-UTERINE PREGNANCY. WITH SPONTANEOUS RECOVERY.

By LESLIE DEWEES, M.D.,
OF SHELBYVILLE, MO.

On May 11, 1887, I was called to see Mrs. K., thirty-four years of age. She was tall and slender,

weighing 130 pounds before her illness. She had been married twice, and was a multipara. Her health previous to April 15th was good, though her menses sometimes appeared at intervals of a fortnight. About April 15th, slight pain and soreness were felt in the right ovarian region. The pain at first was only occasional, but soon became constant and severe. The menses, expected at this time, did not appear, and the pain and soreness steadily increased for two weeks before medical aid was sought.

About two weeks after what should have been the menstrual period—the time at which the pain and soreness were first noticed—the patient discovered a small tumor at the seat of pain. The alarm caused by this discovery induced her to send for a physician, who, after examination, concluded that the menstrual flow was obstructed, a condition that he endeavored to relieve by the use of tents, probes, etc. Several efforts were made with this object in view. The physician at this juncture failing in the regularity of his attendance, the writer was called until the former should resume charge of the case.

My first call was made on May 11, 1887, when I found the patient with a pulse of 120, temperature 102° F., and respiration 28. Anorexia, headache, and pain in the back were prominent symptoms. Pain and formication in the right hip and lower extremity were also complained of. Frequent micturition with a burning sensation, and constipation seemed also to cause considerable annoyance.

Palpation revealed the existence of a tumor the size of an orange, situated to the right of and posterior to the uterus. There was cellulitis, which was circumscribed, or at least chiefly to the right of the median line. The constipation was only partly relieved at this time by the use of enemata.

Her physician now returned, and I did not see the case again until May 26th, when I saw her in a consultation with Dr. A., and learned that on the previous day Drs. M. and O. had seen the patient, and decided that nothing could be done for her more than to administer palliatives. At the time of this visit the patient was excited, and had a high temperature, quick, wiry pulse, rapid respiration, and seemed fearful that an operation of some kind was contemplated. She was decidedly emaciated. The tumor seemed almost centrally located, as large as a small cocoanut, but flattened upon and attached to the uterus, so that no line of separation could be felt between the tumor and that organ.

Complete occlusion of the bowel had existed for several days, and this condition was relieved with the greatest difficulty by means of a soft rubber catheter attached by a piece of tubing to the nozzle of a hand-ball syringe. By means of a long, flexible probe the catheter was passed beyond the tumor. Through this apparatus a half-pint each of sweet oil and soapsuds were injected, and within half an hour a large quantity of liquid fæces was passed, greatly to the relief of the patient.

The speculum revealed an open os, with the lips everted and patulous. A sanguino-purulent discharge came from the cavity of the womb. Much irritation was present from the former use of tents. The uterus was somewhat enlarged, and the fundus was displaced forward and toward the left side. The cavity of the uterus was increased in proportion to the size of the organ, and was markedly convex on the side next to the tumor.

An operation appeared out of the question, unless the inflammatory condition should subside and the patient greatly improve. Attention was, therefore, given to the cellulitis and the general condition, with the hope of operating subsequently. However, consent was never obtained for the performance of an operation.

But little change took place from the date of the above-mentioned visit until near the middle of July, except that the patient became weaker, and perhaps the tumor grew a little larger.

The cellulitis, which, up to this time, was diffuse and severe, began to grow less, and the temperature was lower. Profuse sweats, with an occasional chill, occurred during the latter part of July. The bowels were relieved by the use of enemata when necessary. Micturition was frequent. The urine was scanty, and contained some pus. Operation was still declined by the patient. On August 1st, after having taken an enema, and during an effort to evacuate the bowels, there was a sudden gush of about two quarts of pus and liquid fæces, which materially reduced the size of the tumor. In the pus were found numerous epiphyses, about the size of tomato-seeds, for which they were mistaken by the patient. I was at once notified of this occurcence, but did not see the patient. None of the larger fœtal bones were discharged, except two or three ribs. The tumor refilled, and in about three weeks again discharged through the rectum, but the amount of pus was less, and there were fewer epiphyses.

After this, pus continued to flow from the bowel till about October 1st, when it ceased, and the tumor began to enlarge for the third time, but rather more slowly than before. About December 25th, the tumor showed signs of pointing in the vagina to the right of the cervix, and a few days later it opened spontaneously, discharging a large amount of pus, and several fœtal ribs, about 1¼ inches long, an ulna, and portions of other bones.

I saw the patient again, January 1, 1888, when one of the parietal bones was arrested in the vaginal opening of the pus-cavity, and by its sharp edge was producing much pain. Under an anæsthetic I succeeded in removing this bone, with several others. Owing to the patient's condition all the bones within the sac could not be removed at this time. For a month after this, bones continued to be discharged. The patient's general condition now began to improve, and when I saw her again, on April 22d, she was able to sit up for an hour daily. The appetite was good, the action of the bowels free and regular.

Micturition, however, was still frequent, perhaps due to the contractions of the tissues about the bladder. The tumor had now nearly disappeared, though a hard cicatrix could be felt in its former place. The larger bones, which had been carefully saved, were counted at this time, and all but two or three were found, and it is probable that these had been lost.

The opening from the sac into the vagina had closed, and aside from the possible continuance of the frequent micturition, together with a tendency to the opium-habit, recovery seemed probable.

On May 12, 1888, I again saw the patient, who could then walk without fatigue, but could not stand erect, which she said was due to a "drawing" sensation in the lower part of the abdomen. She weighed about as much as before her illness.

March 4, 1889. The patient had been complaining of a cutting, or stinging, sensation near the median line and half way between the umbilicus and symphysis pubis, and which she thought was caused by another bone, but which on careful examination I found was caused by a tense condition of the tissues. This tension was probably due to cicatricial contraction, and was distinct only when the spinal column was straightened, or bent backward. On flexing the thighs upon the abdomen the cicatrix could be felt, and was not sensitive to pressure.

The uterus was displaced upward so far that it could not be felt with the finger, and could be seen only by dilating the vagina with a pair of forceps passed beyond a Cusco's speculum. The vagina was also much narrowed by the upward traction of the cicatricial tissue.

It was, of course, impossible to determine in this case at what part of the tube the ovum lodged, and there was nothing which indicated the time that the rupture occurred. The latter fact might suggest that the pregnancy was abdominal, or extra-tubal, but from the previous active habits of the patient, together with the location of the tumor when first noticed, I deem this quite improbable.

It would be difficult to determine with any degree of accuracy the length of time that the fœtus lived, but the history and the size of the bones indicate that it died at about the end of the third month.

Doubtless, this case, like many others, might have been cured by an early abdominal section, but after the development of the inflammation there seemed to be no time at which an operation could be safely undertaken.

THE PRODUCTION OF IMMUNITY WITH THE CHEMICAL SUBSTANCES FORMED DURING THE GROWTH OF THE BACILLUS OF HOG-CHOLERA.

BY E. A. V. SCHWEINITZ, PH.D.,
CHEMICAL LABORATORY, BUREAU OF ANIMAL INDUSTRY, DEPARTMENT OF AGRICULTURE, WASHINGTON, D. C.

As a continuation of the preliminary paper on the ptomaïnes from the hog-cholera germ, presented by us to the Chemical Section of the American Association for the Advancement of Science, in August, and published in THE MEDICAL NEWS, September 6, 1890, we present now a somewhat detailed account of the successful experiments in the production of immunity in guinea-pigs which have been made up to date. The work from this standpoint again is of course a practical continuation of the experiments of Drs. Salmon and Smith, made upon pigeons in 1887, in which sterilized culture-media were used for preventive inoculation. We refer further to the bulletin of the Bureau on "Hog-cholera," published in 1889, in which are recorded a number of experiments upon hogs, sterilized culture-media being used for the purpose of producing immunity.

This work of Drs. Salmon and Smith was the pioneer work in preventive inoculation with other than some form of the germ of the disease itself, and the work now recorded was of course under the advice and direction of Dr. Salmon as head of the Bureau of Animal Industry. Without the careful bacteriological study of hog-cholera which has been made by the Bureau of Animal Industry, our work would have been impossible. For our laboratory experiments guinea-pigs were used, as being convenient to handle and susceptible to hog-cholera. They have proved very satisfactory. The material used for inoculation was prepared in the chemical laboratory by modifications of methods already described, and by other methods which will be explained in more detail at some future date. The testing of the materials used, to determine that they were free from germs, and the greater part of the preventive inoculations, were made by Dr. Moore, with such quantities of substance and at such times as we thought best. The autopsies were also made by Dr. Moore, and the work thereby greatly facilitated.

As to the name which should be given to the ptomaïnes and albumins from the hog-cholera culture-liquids, until their chemical constitution is more thoroughly studied, it would seem best, as there are several distinct swine-diseases, to call the ptomaïnes from the hog-cholera germs, as a class, *Sucholotoxins*, and the ptomaïne which appears to be the principal factor *Sucholotoxin* (from the Greek Σῦς, a hog, Χολέρα, cholera, from Χολή, bile, and *toxus*, poison). *Sucholo-albumin* would seem to be sufficiently distinctive for the albumin of these culture-liquids. As Hankin [1] shows, the name *toxalbumin* is hardly the correct one to apply to these substances. We shall, therefore, refer to the ptomaïnes and albumin by the names given above.

The first of our experiments that we will record were made with sucholotoxin.

EXPERIMENTS I.—Two guinea-pigs, each weighing about three-fourths of a pound, were treated with a solution of about 0.05 gramme of sucholotoxin each. The solution was introduced under the skin of the inner side of the left thigh. Immediately after the operation the animal appeared uncomfort-

[1] British Medical Journal, 1889, p. 810.

able, but was not made ill. For a few days there was a rise in temperature and also a slight swelling at the point of inoculation, which, however, disappeared in about five days, and the animal was then well.

Two more guinea-pigs were now selected as checks, approximately of the same size and weight as those which had been treated, and the four animals were then inoculated with 0.1 c.c. of hog-cholera virus each (0.1 c.c. beef-infusion and peptone culture one day old, plus 0.2 of sterile, normal salt solution). This is the dose which previous experiments made in the Bureau had shown to be the proper quantity to kill a guinea-pig in from eight to ten days. The inoculations with the virus were also made subcutaneously in the thigh. The checks died in eight and nine days. Post-mortem examination showed a large swelling at the point of inoculation, infiltration of a purulent, grayish substance into the connective tissue, and necrosis of the superficial layer of the muscles of the thigh. Enlargement and reddening of inguinal glands. Peyer's patches enlarged and pigmented; liver pale and covered with a number of necrotic foci; spleen very much enlarged, dark-colored, and friable. Cover-glass preparations from the spleen and liver showed hog-cholera germs. This was the characteristic appearance of all the check guinea-pigs upon post-mortem examination, and it will not be necessary to repeat these details.

Of the animals which had been first treated with the substance mentioned, and afterward inoculated, one died two days after the last check. Autopsy revealed the following: At the point of inoculation in the left thigh the subcutaneous tissue was infiltrated with a grayish-white substance, and the superficial layer of muscles over the inner side of thigh, and 4 square centimetres of the abdominal wall were necrosed. Liver pale. Spleen much enlarged, dark-colored, and friable. Cover-glass preparations from the spleen showed a large number of hog-cholera germs. Both ventricular walls of the heart were light-grayish and very brittle (necrosed). The other guinea-pig of this set was quite ill for ten days, with a large swelling at the point of inoculation. This finally opened and healed and the animal was quite well within three weeks after the inoculation, and has continued so to date—five months.

Experiments II.—The next series of experiments were made with sucholo-albumin from beef-infusion and peptone culture-media.

Two guinea-pigs were again selected and treated with about 0.008 gramme each of sucholo-albumin. There was a slight rise of temperature in the animals and the formation of a small, hard lump at the point of injection. This disappeared by the eighth day, and the animals were quite well. Two more guinea-pigs were now taken as checks, and all four animals were inoculated with 0.10 c.c. of hog-cholera culture. The checks died within seven days. The post-mortem appearances were practically the same as those noted in the first series. The two guinea-pigs which had been treated with the sucholo-albumin died *ten* days after the checks. This indicates considerable resistance to the disease. Autopsy showed, at the point of injection with the albumin, the subcutaneous tissue thick and reddened. The animals were considerably emaciated. At the point of inoculation a cyst the size of a walnut, and composed of a grayish, purulent substance, was also found. The muscular wall surrounding this was sprinkled with punctiform hæmorrhages. Peyer's patches swollen and pigmented; mucous membrane of small intestine covered with a dry, yellowish, firm layer of mucus; stomach contained a considerable quantity of liquid; liver pale, and showed fatty degeneration; spleen slightly enlarged and dark. Cover-glass preparations showed no germs, but a culture made from the spleen showed hog-cholera germs. Beneath the peritoneum in the region of the spinal column, and in the mesentery was a considerable number of small grayish tubercles. Several other experiments were made by treating guinea-pigs with the albumin in varying quantities, all showing resistance, and subsequently immunity.

Experiments III.—Three guinea-pigs were treated with sucholo-albumin, 0.1 gramme being given to each, subcutaneously in the thigh. The albumin for two of the animals was derived from cultures containing blood-serum, the albumose given to the third was from ordinary beef-infusion peptone culture. Ugly ulcers formed at the point of inoculation, which healed, however, in from ten to fourteen days, and the animals with the exception of a slight rise of temperature were well.

Two checks were again selected and the five animals were inoculated with 0.1 c.c. hog-cholera virus. The checks died respectively in eight and ten days from hog-cholera. The animals which had received the preventive treatment were slightly ill for a few days with swelling at the point of inoculation, which finally opened and then healed nicely, and within a week the guinea-pigs were well.

Three weeks after the inoculation, one of these animals was chloroformed and examined post mortem. Not the slightest scar could be discovered, all the organs appeared perfectly normal, and no germs were found.

Experiments IV.—Four guinea-pigs were treated, two with a mixture of sucholotoxins, two with sucholotoxin and albumin. The injections were made as before, subcutaneously in the thighs, and at intervals extending over a period of four weeks. The sore caused by each injection was allowed to heal before the next one was made. After the animals

had recovered from the last treatment two checks were selected, and the six were each inoculated with $\frac{1}{10}$ c.c. hog-cholera virus. The checks died, one in eight and the other in ten days, the post-mortem examination showing characteristic hog-cholera lesions. The animals having the preventive treatment were ill for about four days, those that received only the sucholotoxins being more dull than the others. There was also slight swelling at the point of inoculation with the germ, which subsided in ten days, after which the animals were perfectly well, and have remained so—four months.

Experiments V.—Six guinea-pigs were inoculated for this experiment, two with solution of the sucholotoxin and four with a solution of the mixed sucholotoxins. The sucholotoxin solution produced only slight local lesions, while the mixed toxins caused ulceration at the point of injection which did not heal for two weeks. The treatment in this case again extended over a period of from three to four weeks. The animals having by this time recovered, the test-experiment with hog-cholera virus was tried. Four of the animals mentioned above were taken—two from each set—and also two checks, and the six were inoculated. The checks died in eight and nine days, the autopsies showing the characteristic conditions of death from hog-cholera. Those that had the preventive treatment were ill and dull for from four to six days after the inoculation. At the point of inoculation there was also some swelling and infiltration, very slight, however, compared with the similar swelling on the checks. In the treated animals the swelling sloughed and healed, and within ten days after the inoculation they were perfectly well. To test the resistance of the animals that had been treated by this method, to ordinary exposure the following experiments were conducted.

Experiments VI.—Two guinea-pigs that had received the preventive treatment, two blanks—*i. e.*, animals that had received no treatment—and two check animals that were inoculated with hog-cholera virus were placed in one large cage. The checks became ill and died in eight or nine days from hog-cholera. During this time the cage was cleaned only three times, so as to give full and free opportunity for contagion. One week after the checks had died one of the blanks became ill, and died within ten days. The autopsy showed hog-cholera lesions. The second blank became ill a few days after the first blank succumbed, and died within thirty days. The animals which had the preventive treatment are now and have been quite well, though continually exposed for five weeks to every opportunity for contagion.

Experiments VII.—These experiments are a step in advance of those already recorded, and although not quite so conclusive, indicate that the proper methods have been adopted.

A pure chemical compound prepared synthetically in the laboratory, was used for treating the guinea-pigs. Three animals were taken, and this compound was administered to them by the method already used. There was a slight rise in temperature of the animals and swelling and soreness at the point of injection. After this had healed these animals and two checks were inoculated with $\frac{1}{10}$ c.c. of hog-cholera culture. The checks died in eight and nine days. The animals which had been previously treated became ill, two dying five and six days after the checks. The third entirely recovered.

Post-mortem examination of the two that died showed the following: At the point of inoculation the skin had sloughed away over an area of 1 sq. cm. The superficial muscular layer was necrosed over an area of about 3 sq. cm. and to a depth of 1 mm., lymphatics in the fold of the knee much enlarged; Peyer's patches enlarged and pigmented; spleen *very slightly enlarged and not discolored;* kidneys reddened; lungs normal. Cover-glass preparation from the spleen showed a few hog-cholera germs. On both sides of the spinal column were several grayish tubercles, from $\frac{1}{4}$ to 2 mm. in diameter, lying just beneath the peritoneum. This material is being more fully tested, and experiments which promise to be successful are also being made upon hogs. Autopsies made from the animals of Experiments VI., three or four weeks after their recovery, showed that the parts were perfectly normal, not even a scar being left upon the skin, and the immunity produced was therefore *perfect.*

It is important to add that in all the experiments great care was taken that the solutions used were free from germs, cultures always being made. In cases in which the albumin is used this is particularly important. A single precipitation with absolute alcohol does not suffice to destroy the germs, and it is necessary to free the solution from germs by means of a Pasteur filter, or in some other suitable way. Therefore experiments made with material which has not been tested for germs are practically of no value. As to the poisonous character of the ptomaïnes, a single large dose is sufficient to kill a guinea-pig in from one hour to two days. The autopsy of a case of this kind is as follows: Liver, pale and fatty; subcutaneous tissue over abdomen, necrosed and infiltrated; muscle, soft and friable. Other organs apparently normal.

The experiments here recorded show:

1. That in guinea-pigs *complete immunity* from hog-cholera can be produced by *chemical inoculation.*

2. The sucholotoxins and sucholo-albumin are equally effective in this respect, and a mixture of

these two products gives greater immunity than either used by itself. The effect of the albumin in producing immunity from anthrax has already been pointed out by Hankin, his experiments being very successful.

3. The sucholotoxins given in large doses produce death. To produce immunity it is necessary that they should be administered in small quantities at a time and at frequent intervals, the system being in this way accustomed to the poison and enabled to resist it.

Further study in this interesting line of work is in progress.

The tabulated results of the foregoing experiments are appended:

Tabulated Results of Experiments in Producing Immunity from Hog-cholera in Guinea-pigs.

Number of experiment.	Material used for treatment.	Hog-cholera virus used for each animal	Number of animals used.	Number of checks.	Number of days between inoculation with virus and death of checks.	Result in treated animals.
I.	Sucholotoxin . . .	0.10 c.c.	2	2	8 and 9	1 died in 11 days. 1 recovered.
II.	Sucholo albumin . .	do	2	2	7	Died in 17 days; great resistance.
III.	Sucholo-albumin . .	do.	3	2	8 and 10	Recovered; immunity.
IV.	1. Sucholotoxins . . .	do.	2			Recovered. immunity.
	2. Sucholotoxin and albumin	do.	2	2	8 and 10	
V.	1. Sucholotoxin . . .	do.	2			
	2. Sucholotoxins . . .	do.	2	2	8 and 9	Recovered; immunity.
VI.	Sucholotoxins . . .	do.	2	2 blanks		Blanks died in 18 and 30 days.
				2 checks	8 and 9	Others not affected; immunity.
VII.	Pure chemical . . .	do.	3	2	8 and 9	Two died in 13 and 14 days. Third recovered; immunity.

TWO CASES OF FRACTURED SKULL.

Recovery in One; Death from Chloroform in the Other.

By THOMAS MANLEY, M.D.,
visiting surgeon to the harlem hospital, new york.

Although traumatic lesions of the cranial shell, in large cities, are of frequent occurrence, those of the kind here described are rarely seen. Both cases are singularly interesting in causation, age of the patients, location and similarity of the lesions, clinical history, pathological conditions, and in the state of the nerve-centres when the patients came under observation.

Now, that cerebral localization is being investigated with great care and minuteness, it is interesting to note how far experiments on the lower animals can be utilized for clinical purposes in man. And further, since the two Hyderabad Commissions have given their, rather conflicting, but, nevertheless, very full and exhaustive, reports on the lethal action of chloroform, it is timely to note precisely the phenomena which attend the mortal action of this drug on man.

The two boys who are the subject of this history were injured on the afternoon of June 11, 1890. They, with eight or ten companions, found a truck, used for moving stone, standing by the roadside. They got hold of it, some pulling and others pushing, and dragged it up a steep hill. Reaching the summit, they turned it around, got aboard, and let it go down. What the ultimate fate of all the adventurers was after they started on their journey down the hill we are unable to record, but a police officer, hearing the noise of the truck and the screams of the children, hurried into the field, to find the truck capsized near the foot of the hill, and two boys lying about midway down the declivity, both being unconscious, and one apparently dead. The Harlem Hospital ambulance was sent for, and, on its arrival, Dr. F. P. Hammond, the ambulance-surgeon, found W. P., the older boy, apparently moribund. He breathed only in gasps, at long intervals; the pulse was absent in one wrist, and in the other only a feeble flicker could be detected. Respiration was stertorous; blood mingled with saliva was oozing from the mouth and nose, and there was a bloody fluid flowing from the left ear. Dr. Hammond vigorously stimulated the patient by hypodermic injections, sponged out the mouth, and douched the face with cold water. The little fellow gradually reacted, and in half an hour was in the ambulance.

The other boy, B. J., lay on his back, bleeding freely from a wound of the head, and was also insensible. His general condition was not bad, and before he reached the hospital he regained consciousness.

In each case antiseptic dressings were immediately applied with as much care as possible.

I saw the cases three hours after they were admitted to the hospital. They were then perfectly conscious, but could not give a clear account of the accident. The older boy was still suffering from shock. His pulse was slow, 60 beats to the minute, and the pupils were markedly contracted. The outline of the features was regular, and the nose, ears, and lips of an ashy pallor. The extremities were cool, with marked, though not total, abolition of the reflexes. There were areas on the inner side of the thighs in which sensation was wholly lost, and

others on the palmar surface of the hands where, though sensation was intact, mobility was lost. When asked to move a limb he did so slightly, but with great effort, and on one side only. He was somewhat deaf. Immediately behind the right ear there was a scalp-wound exposing the bone. There was free hæmorrhage from the nose, mouth, and left ear, and from the latter the blood was somewhat serous and straw-colored in character.

His condition indicated fracture of the base of the skull, probably with free hæmorrhage into one of the great cavities of the body.

He was brought into the operating-room, and, as a preliminary to the examination of the wound, we adopted the recommendation of Dr. F. S. Dennis, and shaved the entire scalp, in order that antisepsis might be more rigorously carried out. At the seat of injury we found a fracture which was almost circular, with its greatest diameter from before backward. The large disk of bone was driven into the brain, being wholly detached at its circumference. The position of the fracture was on a line with, and immediately behind, the concha of the ear. The skull surrounding the fracture was fissured in a radiating manner, the fissures extending backward and toward the base being the deepest and most widely separated. Considering the cranio-cerebral topography of the lesion, it was evident that the left lateral sinus was nearly in the centre of this depressed plate of bone, which was evidently a part of both the parietal and occipital bones.

The safest course to pursue was now a question which did not permit much deliberation. Whether, bearing in mind the close proximity of the large venous channel, it might not be safer to cleanse the parts thoroughly, and let the fracture alone—as, independent of the eyes, we had no distinctive indication of cerebral pressure—or whether it would not be better to trephine at once, were the questions which had to be decided. We all know that hæmorrhage from vessels within the skull is sometimes difficult or absolutely impossible to check. We know, too, that an aseptic blood-clot—if not large or within the brain—often undergoes disintegration, organization, or absorption, without causing serious harm. We know further—though, unfortunately, operators are loath to report such cases—that an operation to remove depressed bone, or large blood-clots, may in itself be fatal. I have had, in about one hundred and fifty fractured skulls which I have treated, two such cases.

In one we were removing a large fragment of bone driven into the brain, almost at the confluence of the cranial sinuses. The spicula of bone came out quite readily, but it was followed by a deluge of blood which could not be controlled. In the other case, I trephined above the ear, over the temporo-parietal articulation, for symptoms of compression following an injury. We came at once, upon a very large intradural coagulum. After I had gnawed away, with the rongeur, sufficient bone to remove the clot, I commenced to crush it gently with the fingers, working cautiously until I believed it was nearly displaced, when a jet of dark, tarry blood welled up from the bottom of the space left by the clot. It came in torrents, and our compresses and hæmostatic forceps were useless. We had re-opened a large trunk which the clot had plugged, and it was fatal. I may add, that I have heard of similar disasters, in the hands of others, but they have not been published.

To return to the present case. I decided to try to elevate, as the fragment was driven in so far that I was able, by chipping off enough bone from the overlapping margin, to get my elevator between the dura and the skull, using the edge as a fulcrum. Happily, I was able to raise quite easily the fragment to its normal position. Very little blood was lost, and the wound, with the entire cranium, the neck, and the eyes, were enveloped in soft antiseptic gauze.

During the night, following the operation, the patient moaned, groaned, cried, and vomited. He had two or three sinking spells and became cold; but Dr. Guest, the house-surgeon, used heat and stimulants energetically, and the boy reacted.

I saw him at 10 A.M., June 17th. At this time it seemed that he could not recover. His pulse was 186, and his temperature subnormal, and he had the heaving respiration which Bell[1] has so well described, as a sure precursor of death. But by noon he commenced to rally and he has made a good recovery; although both pupils are dilated, and he has double convergent squint. Hearing has been perfectly regained and there is no trace of paralysis.

It is interesting to note that in this case we had almost unequivocal evidence of fracture through the base of the skull, and yet the patient made a good recovery, the only organic disturbance at this date being confined to the organs of vision.

Dr. Ferrier in his recent Croonian lectures on "Cerebral Localization," tells us that "the occipito-anterior region is the visual area of the cortex." It seems that this conclusion has been reached, mainly by experiments on monkeys and clinical observations on man. Considering the location of the lesion, in the case just described, and the marked disturbance of the visual organs, at the time of the injury and since, I think that the patient's condition is strong evidence in favor of the correctness and accuracy of the statement made by Dr. Ferrier.

There can be no doubt that considerable blood escaped into, and through the cerebral substance, and that, following the line of fracture, it ultimately lodged in close contact with the base of the pons Varolii and the corpus pyramidale, where, by pressure, it interfered with the nutrition and functions of the ocular nerves, notably and persistently with the abducens.

With the ultimate reduction and absorption of the effused blood, I expect perfect restoration of accommodation.

[1] Sir Charles Bell: Nervous System, second edition, p. 203.

The younger of the two boys, B. J., when I saw him, had a large hæmatoma directly behind the right ear, in precisely the same situation as the wound in the preceding case, except that the tumor extended slightly downward into the cellular tissue of the neck. The house-surgeon had made a diagnosis of fracture of the skull. The patient had almost no constitutional disturbance, but there had been nasal hæmorrhage. He did not complain of pain, and moved about in bed without difficulty. He was slightly pale, however, and vomited twice after entering the hospital.

The contour of the hæmatoma, with its firm, bevelled border and depressed centre—characters common to all cranial hæmatomata—and the total absence of any cerebral symptoms, led me to believe that there was no fracture.

The scalp over the swelling was shaved and cleansed, after which I made an incision into the tumor and evacuated it, when I found well-marked linear fractures; one running antero-posteriorly, intersected by another passing toward the base. The greatest extent of fracture was in the occipital bone, extending but two or three lines into the parietal. There was very slight depression of the upper boundary of the divided plate. Under strict antisepsis, I closed the incision with a continuous suture, and applied the usual dressing.

The following morning the patient was in excellent condition, and speedy recovery seemed probable. At noon of this day he vomited. At 2 P.M. the temperature was 102°. Internal squint of the left eye, varying in degree, was noticed, and the pupil was slightly dilated. He was able to urinate and had no paralysis of the extremities.

On June 17th it was noted that he had passed a restless night. At 8 A.M., temperature was $103\frac{1}{2}°$, and at 10.40 A.M. was the same; at 12.30 P.M. temperature was $103\frac{3}{5}°$. At 1.20 A.M., June 19th, temperature was $103\frac{3}{5}°$; at 2 P.M. temperature was $104\frac{1}{5}°$.

I saw him at 3 P.M. on this date. He now had well-marked symptoms of compression with meningitis. His pulse was very rapid, the temperature high, and he was incessantly moving about in the bed. Marked congestion of the conjunctival vessels clearly indicated cerebral hyperæmia.

His mental condition at this stage presented many features of interest. He would have intervals of repose, in which he would lie on his back, with his eyeballs immovably set and the lids widely opened, muttering incoherently to himself. Every few minutes he would arouse from this condition for a short time. When asked how he felt, he would look up, answer intelligently and complain of great pain throughout his head. Then he would immediately lapse into a semi-conscious condition with his eyes open.

It was only too apparent that serious mischief had resulted from the injury, but whether from local conditions, as the pressure of a shattered internal table, or of a clot, was difficult to determine. It was too early for pus to have formed.

I had recently seen two cases of traumatic meningitis in boys: one from fracture of the skull, the other from an infected scalp wound. In both there were well-defined cortical lesions, with all the typical symptoms. On trephining these cases, however, nothing was found but a general meningitis, a diagnosis confirmed by autopsy.

In the present case, it seemed to me that there were no symptoms which could be relied upon as an indication to operate. Besides, in refraining from operating I followed the opinion of the veteran French surgeon Verneuil, who says: "Qu'on fasse dans le laboratoire toutes les expériences, qu'on vondra; mais qu'on se garde les transportes au lit du malade."[1] This entirely harmonizes with my own experience.

I was anxious to ascertain the condition of the wound, and, if I found indications of incipient ostitis, to trephine, as recommended by Bryant.[2] My intention was to remove one or two sutures, inspect the line of incision, and reclose the wound without using an anæsthetic. But I found the tissues behind the ear puffed, œdematous, and discolored. On freeing two or three of the sutures I saw that the whole wound was in a bad condition. The edges were covered with a dirty grayish exudate, and were slightly everted, and the whole had an appearance indicative of disease beneath the bone.

As I saw that our operative procedures would be somewhat tedious, and as the patient was keenly sensitive to pain, and, excepting his temperature, in a good general condition, I decided to give him a few whiffs of chloroform, presuming that this would be taken with less resistance and more rapidly than ether, and that it would not congest the vessels of the brain.

Dr. F. P. Hammond, third assistant-surgeon of the hospital, an extremely cautious and painstaking man, administered the chloroform by sprinkling a few drops on lint placed in a tumbler. I had denuded the skull, and removed a piece of bone with a small trephine and rongeur, when I noticed, in an instant, several terrible changes. The patient ceased to breathe: his features were black and bloated; he foamed at the mouth; the eyes bulged, and plainly he was asphyxiated. Feeling for the radial pulse, I was amazed to find it full, slow, and regular—about 60 to the minute. We had before us a genuine case of chloroform-poisoning, with all the symptoms which have been described by other authors and investigators.

The *respiratory centres yielded first.* This was clear and unmistakable. All our resources were immediately applied, namely, artificial respiration, inversion, inhalation of nitrite of amyl, hypodermic injection of atropine, drawing the tongue forward, douching of the face, and friction of the body. After an interval of what seemed five, though in reality not more than two, minutes, the patient gasped several times. A little later he breathed again, but very irregularly, and would cease unless artificial respiration were continued. Respiration seemed quite fairly reëstablished at one time. It was interesting

[1] Mercredi Médical, May 27, 1890.
[2] Surgery, third edition.

to note the condition of the brain in the meantime. With dyspnœa and apnœa the brain-tissue crowded into the gap made by the rongeur. The vessels were enormously distended, and of a deep black color. With partial return of respiration the brain gradually receded, and the vessels collapsed to their usual calibre and assumed their normal tint. I had noticed, however, before the symptoms of asphyxia developed, that the cerebral vessels were greatly distended.

No more chloroform was given after the first lethal symptoms were manifest.

Although respiration was partially restored, the deep cyanosis remained, the breathing continued stertorous, and frothy mucus, tinged with blood, oozed from the mouth. In about five minutes, or possibly a little longer, there was another break in the rhythm of the breathing. This time all our efforts were futile. As in the first instance, the pulse continued to beat fully two minutes after the patient was apparently dead, or rather had ceased to breathe.

Although I have witnessed the administration of ether and chloroform a great many times, this is the first case in which I have seen death immediately and directly attributable to the anæsthetic.

This case so clearly and absolutely proves that the lethal action of chloroform begins by benumbing the respiratory centres, that no one can question it. The condition is a veritable asphyxia. The phenomena, to the eye, are precisely the same as those seen in cases of spasm or stenosis of the larynx; in persons who have been submerged in water, and in those struggling through an epileptic fit, when the laryngeal muscles are temporarily convulsed.

It was in the *initial* stages of anæsthesia that the respirations ceased, and after very little chloroform had been given. The vaso-motor nerves and the cardiac centres were affected *consecutively*. The blood, surcharged with carbonic acid, soon destroyed the vitality and irritability of the pneumogastric and sympathetic nerves.

Clearly perceiving, then, how the action of the drug manifests itself, we are in a position to deal with it intelligently. We should act with two objects in view: first, to unload the vascular system, and the brain; and, second, to keep up respiration. It may be said that when breathing ceases the respiratory centres are paralyzed, and all efforts at resuscitation are useless.

But we see many cases which prove that this is not always true. A case of tracheotomy, for instance, reported by me in the *New England Medical Monthly*, January, 1890, is an illustration. In this case, after the trachea was opened, the patient inspired blood. He ceased to breathe, but the pulse continued to beat for some time. With the body limp and apparently lifeless, we worked fully five minutes with artificial respiration, when the patient gasped, and shortly revived, ultimately making a good recovery.

A surgeon related to me, how in a case of croup, he called in a consultant, who advised tracheotomy. Some blood was drawn into the windpipe, the infant had a terrible convulsion, and turned over apparently dead. The consultant, quite shocked at the result, and fearing the maledictions of the parents, immediately left. But the attending physician remained at his post, wiped out the bleeding opening, and with his own lips blew into the child's trachea. In a few moments—fully ten, he thinks—the child commenced to breathe, and finally made a good recovery.

In the case reported above, had we worked more diligently at renewing the air in the lungs, and given less attention to the incision, the result might have been different. But we were too confident: besides, I had to search for and ligate a small meningeal vessel which commenced to spurt freely. When respiratory paralysis occurred for the second time, had we done a tracheotomy and used the invaluable apparatus of Dr. Joseph Fell, of Buffalo, for forced respiration, I am confident our patient might have been saved.

The unfortunate termination of this case has more strongly than ever convinced me of the imperative need of an experienced and trained anæsthetizer—one who will give his whole attention to administering anæsthetics; a man of good judgment and who is solely concerned with the patient's general condition. He should be specially licensed, and the administration of an anæsthetic, other than in an emergency, by anyone not professionally and legally qualified should be regarded as a misdemeanor. The present custom is dangerous, and little short of being positively criminal. Usually the anæsthetic is committed to the junior assistant, who is almost wholly ignorant of practical work. He is often more interested in the operation than in giving the anæsthetic, so that when he finally looks into his patient's face, and feels the pulse, perchance the patient is dead. Let us hope that a reform in this matter will soon be accomplished.

The physical characteristics of the two fractures demand only brief mention. From a medico-legal point of view, they are full of interest, and also to those who may be called on, in a court of justice, to testify as to the quality and direction of force brought to bear in traumatic lesions of the skull.

It will be noted that the children were found alone and unconscious, in an open field. No one has been found who saw the accident, or at least who will admit that he saw it.

In each case, so similar were the osseous lesions in extent and direction, that it would certainly seem that they were inflicted with precision and deliberation. The violence must have been great and concentrated. Its point of impact was very lim-

ited, and chiefly in the direction of the base. There were no rocks in the place where the boys were injured. It is hard to conceive how these boys, of light weight, precipitated from a stone-truck, about two feet from the ground, to soft, elastic turf, could receive such injuries. Did the wheels pass over their necks or heads? There were no abrasions or contusions except those immediately over the wounds, and if the wheel had passed over their heads the wounds would have been larger.

Had not the boys regained consciousness, or had they been found dead, so that no history could have been obtained from themselves, the state of the integument, the shape, direction, and extent of the fractures would have thrown no light on the injury.

These cases would seem to prove that there are serious bone-lesions in which we are absolutely unable, from the condition of the parts, to say what was the nature of the force, or in what direction it was applied; hence the importance of the surgeon proceeding with great caution when giving testimony, on which great consequences or even a human life may depend, when such testimony is merely presumption or hypothetical premises.

REPORT OF A CASE OF SPONTANEOUS RECESSION OF A LARYNGEAL PAPILLOMA AFTER TRACHEOTOMY.

BY WARWICK M. COWGILL, PH. B., M.D.,
OF PADUCAH, KENTUCKY;
FORMERLY CLINICAL ASSISTANT AT THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE.

MR. LENNOX BROWNE, in his work on *Diseases of the Throat*, under the heading of "Treatment of Benign Growths of the Larynx," warns against harsh methods in attempting their removal. He says:

"The number of persons to whom the advice to wait and watch is given, must be very small, but, without doubt, there is a very large proportion of cases which never require treatment, and, if left to themselves, never assume a serious aspect. There is no reason to doubt that while many of these formations remain thus stagnant a large proportion would, on no less authority than that of Virchow, if untreated, frequently disappear spontaneously, being subject, as they are, to slow atrophy and resorption."

Dr. G. Hunter Mackenzie,[1] of Edinburgh, has reported a case of spontaneous disappearance of laryngeal growths after tracheotomy.

"The case was that of a boy aged five years, who, in 1883, underwent tracheotomy for laryngeal stenosis from warty growths. The growths disappeared after the canula had been worn for a year. The canula was then removed and complete recovery ensued, and without the development of sequelæ."

I wish to add the following:

In the latter part of April, 1885, I was called in consultation by Dr. John G. Brooks, of Paducah, to see Minnie B. I found a delicate, pale, little girl, six years of age, laboring for breath, inspiration being somewhat more difficult than expiration. I at once made a laryngoscopic examination. The child was making the fullest exertion in its power to inhale sufficient air to support life, and was naturally averse to any additional interference with respiration, so that it was impossible for me to get a good view of the larynx. But I was able to recognize an obstruction in the upper portion of the larynx. The nature of the obstruction I did not then attempt to determine, though I believed that it was a neoplasm. The history of the case was, briefly, that difficult breathing had been first noticed four years previously to this time—that is, when the child was but two years old—and that the difficulty had slowly increased up to the time of my examination. I advised tracheotomy to relieve the urgent dyspnœa, and as a preliminary step toward removing the obstruction.

On May 5th, a few days after I had first seen the child, I performed laryngo-tracheotomy, which gave instant relief to the obstructed respiration, and in a few moments the pale, bluish face and the blue lips were red with the now well-oxygenized blood. Not a bad symptom followed, and on the eighth day after the operation the child was allowed to return home, about five miles into the country.

As soon as she was sufficiently strong I had her brought to my office for further examination. At this time, with the aid of cocaine, I obtained an excellent view of the larynx. In the lumen of the larynx, above the vocal bands, was a pale-red, mulberry-like growth, about the size of a large filbert, and almost filling the cavity. From its appearance, slow growth, and the age of the patient, we arrived at the conclusion that the neoplasm was a benign papilloma. At this time, and afterward, I made repeated attempts to remove the growth with forceps, but the patient being so young, and much frightened by the instruments, I did not succeed in my attempts. After the ineffectual attempts to remove the growth *per vias naturales*, I suggested thyrotomy, but the parents strongly objected to any further cutting operation, as the patient seemed to be doing so well.

The child grew stronger and suffered but little inconvenience from wearing the tracheotomy tube. I, of course, admonished the parents as to the danger of the child breathing unwarmed air through the tube, and she was well protected from exposure to sudden atmospheric changes.

The condition of the case changed little, if at all, for about two years. At the end of this time, however, the mother believed that the child could talk a little more distinctly, and on examination, I thought I detected some diminution in the size of the growth. From this time on we waited and watched. The growth gradually receded until, in December, 1888, three years and eight months after the tracheotomy, the only remaining sign was a small papilla, about one line in length, projecting from the posterior wall of the larynx. The canula was then finally discarded, and the artificial opening

[1] Lancet, April 6, 1889. Abstracted in the Journal of Laryngology and Rhinology, June, 1890.

was closed. Up to the present writing there is no sign of any return of the growth.

In concluding, I wish to call attention to the term *spontaneous*, as used in this report. Strictly speaking, it can hardly be said that the growth disappeared spontaneously, for if irritation of the mucous membrane is one of the most active causes in the production of papillomata of this structure, then the absence of irritation upon a papillomatous growth—or, in other words, rest, as was secured in this case, by tracheotomy—must have been an active agent in producing its recession.

MEDICAL PROGRESS.

Extra-uterine Pregnancy.—The following case, reported by BOISLIEUX, of Paris, in the *Nouvelles Archives d'Obstétrique et de Gynécologie* of August 25, 1890, was one of extra-uterine pregnancy at the third month, terminating spontaneously with the expulsion of the decidual membranes. The patient had been previously subject to pelvic peritonitis, and had been treated for this disease. Six years before the occurrence of extra-uterine pregnancy she was delivered of a living child after a normal labor. At the end of the third month in the extra-uterine pregnancy a few drops of blood were lost, and ergot was given to control the hæmorrhage, which, however, shortly returned, requiring a second administration of ergot and opium by injection twice a day. Some days later the patient appeared exsanguinous, the pulse was small—120 beats a minute, and there was great pain in the right groin; the uterus was anteflexed, and the fundus was bound down and immovable, being incarcerated below the promontory of the sacrum. On palpation a distinct swelling could be found on the right side pressing down into Douglas's pouch.

The diagnosis made was that abortion was imminent, and, as a consequence, the ergot was stopped and the opiates continued; the vagina was also packed with iodoform-gauze. After this the pain in the uterus ceased, but persisted in the right groin. There was no trace of lymphangitis or œdema.

Several days later, after persistent pain for six hours, there was expulsion of the fœtus and membranes.

Microscopical examination of the membranes which were expelled showed that they were, beyond all doubt, derived from tubal pregnancy. The swelling in the groin rapidly decreased in size, and the woman ultimately entirely recovered.

Flushing the Bladder without a Catheter.—STAFF-SURGEON ROTTER, of Munich, recommends the following process of flushing the male bladder, which obviates the introduction of a catheter, and makes it impossible to introduce septic matter into the bladder. An irrigator, filled with a quart of some disinfecting, and perhaps slightly astringent, liquid, at a temperature of from about 82.5° to 86° F., having a tube six feet or more in length, with a perforated and somewhat pointed end—which, according to the size of the meatus, is covered with more or less gauze previously saturated with the disinfecting fluid and greased with antiseptic vaseline—is used. For patients with a very small meatus a thin, gutta-percha drainage-tube a few inches in length is attached to the end of the tube, which is exhausted, and then completely filled with the warm fluid. The patient is told to micturate, if possible, and then to lie on his back, with his legs a little drawn up and his pelvis supported. The end of the tube is then introduced into the urethra to the depth of about an inch, and there held by the physician, who continually presses the glans against the tube. The irrigator is then raised, first three feet high, and then six feet, and in from half a minute to two minutes, or, in patients with a very strong sphincter, in three or three and a half minutes, the liquid begins to flow into the bladder. The amount used is easily determined if the irrigator is made of glass; or, if not, by the vibration that is communicated to the corpora cavernosa. If it is intended to fill the bladder completely, percussion, the appearance of the bladder above the symphysis, and, in many cases, the patient's sudden desire to micturate, will give the necessary information.—*Lancet*, August 30, 1890.

Condurango.—In a paper published in the *Bulletin Général de Thérapeutique*, of August 30, 1890, GUYENOT, after a careful study of this drug, reaches the following conclusions:

1. In the form of a powder it is very efficient in the treatment of painful affections of the stomach, and particularly when they are due to ulceration or irritation of the mucous membrane of this organ.

2. In cases of cancer of the stomach, which have been reported as cured by condurango there has certainly been an error in the diagnosis, the real condition present being in all probability that of gastric ulcer.

3. The active principle of condurango has a curious and interesting action, for it produces a true experimental locomotor ataxia.

Guyenot recommends this drug in the following forms:

In powder it may be given in the dose of from a half to one drachm in capsules, or the tincture may be given in the following manner:

R.—Tincture of condurango . 5 drachms
Syrup of bitter orange peel . 2 ounces.—M.

Sig. A teaspoonful to a dessertspoonful three times a day; or the bark may be made into an infusion by adding half an ounce to three teacupfuls of water and taking one teacupful morning and night; or, a third method of administration consists in taking a half ounce of powdered bark, and adding thereto fifteen drops of hydrochloric acid, and adding to this five ounces of syrup of bitter orange. Of this last mixture a teaspoonful may be taken every two hours.

Use of Iodides in Infantile Scrofulosis.—Tincture of iodine may be administered to very young infants in the dose of a drop a day diluted with a small quantity of barley-water or milk. BESNIER uses iodoform in minute doses for the same purpose in infants.

Remedy for Dyspnœa.—HUCHARD states that aspidospermine, the active principle of *aspidosperma quebra-*

cho, is a useful remedy in the treatment of dyspnœa. When powdered it may be prescribed in the dose of one-half to one and one-half grains a day, or it may be injected hypodermically provided that the hydrochlorate is employed, the solution being made by adding seven grains of the drug to every two and a half drachms of distilled water.

Snuff for Coryza.—In the *Journal de Médecine de Paris*, Aschmann recommends the following powder in coryza:

R.—Finely-powdered naphthalin		6 drachms.
" " boric acid		6 "
Powdered camphor	. .	15 grains.
Extract of violets	. .	15 "
Essence of rose	. .	10 drops.

To be used as a snuff in coryza.

The Human Body Forty Years under Water.—A very interesting report has just been issued by Dr. König, "Gerichtsarzt" (judicial physician) of Hermannstadt, on the state in which the human subject, after forty years' immersion in water, may be found by the physiologist. In the revolutionary upheaval of 1849, a company of Honvéds, as the Hungarian militia are called, having fallen in the vicissitudes of war, were consigned to the waters of the Echoschacht, a pool of considerable depth not far from Hermannstadt. Their bodies have recently been brought up to the light of day, and subjected to a careful and minute investigation from the physiologist's point of view. Dr. König found them in perfect preservation, without a single trace of any decomposing process. Externally, they had the appearance of having been kept in spirit. The epidermis was of a whitish-gray color; the muscles rose-red, feeling to the touch like freshly-slaughtered butcher's meat. The lungs, heart, liver, spleen, kidneys, bladder, stomach, and alimentary canal were of the consistence of those in a newly-deceased corpse; while the brain was hard and of a dirty gray color, as if preserved in spirit. Structurally, the organs retained their outline perfectly, and were so easily recognizable in tissue as well as configuration that, according to Dr. König, they might have been exhibited for "demonstration" in an anatomical lecture-room. After forty-one years under water these are indeed remarkable phenomena. The large intestine contained fæces of a yellowish-brown color, quite unaltered and inodorous; while the bladder was partially filled with straw-colored urine. But perhaps the most significant feature disclosed by these corpses is the following: In their interior a large amount of chloride of sodium, crystallized in cubes, had been deposited and fixed on the several tissues and organs, and this salt had not penetrated, mechanically, into the dead bodies from without. In the completely closed and perfectly unimpaired pericardium, and also on the outer surface of the heart itself, crystals of the same kind were found. This, according to Dr. König, clearly shows that, in the water, particles held in solution may pass through the skin and the muscles, and find their way into the most deeply-seated organs. Herein, he adds, we have confirmatory proof, if such were needed, that the specific virtues of mineral baths exercise in this way their salutary effect on the internal economy of the bather. There is a notable difference, however, between the time spent in the bath by an ordinary bather at a "Curort" and the forty-one years during which the Honvéds remained under water. The phenomenal quietness of the Echoschacht may also have been a material factor in this impregnation of the corpses with chloride of sodium. But, with every allowance for such considerations, Dr. König has furnished a striking illustration of the permeability of the immersed human subject to salts in solution, and we hope his painstaking researches will lead to others in the same important direction.—*The Lancet*, August 9, 1890.

On the Assimilation of Natural and Artificial Butter and Tallow in Healthy Persons.—In order to throw some light on this matter, Dr. Nikolai F. Florin, of St. Petersburg, has carried out (*St. Petersburg Inaugural Dissertation*, 1890, No. 24, pp. 50) a series of elaborate and most careful comparative experiments on nine men (including himself) aged from 21 to 35 years, and a lady (the author's wife) aged 27 years. In each case the experiment lasted ten days, being divided into two periods of equal duration. In seven of the ten experiments, during one of the periods, artificial butter (obtained from a local manufactory and prepared after somewhat modified methods of Mége-Mouriès and Mott) and during the other period genuine butter was given. The remaining three persons were similarly taking artificial butter and tallow. Besides the fats, the dietary consisted of cooked meat, fatless beef-tea, thick gruel (*Kasha*), wheat or rye bread, the whites of eggs, tea, sugar and salt. The essential outcome of the researches may be given as follows: First. The assimilation of natural butter oscillates between 94.74 and 97.81 per cent. (of the fat ingested), averaging 95.89; that of an artificial butter, between 92 and 95.25, averaging 94.82; that of tallow, between 92.55 and 93.07, averaging 92.75. Second. Therefore artificial butter is not assimilated by healthy adults as well as a genuine one (the difference amounting to 2 per cent.), but better than tallow (at the rate of 1.91 per cent.). Third. Artificial butter is tolerated by healthy people quite well (if it is prepared of the best materials and under the strictest precautions in regard to cleanliness, etc.). Fourth. Nevertheless there is no necessity whatever for artificial butters—at least so far as Russia is concerned. Hence, the government should prevent the establishing any new butter factories, while exercising the strictest sanitary supervision of those already in existence.—*St. Louis Medical and Surgical Journal*, September, 1890.

Ointment for Pigment Spots of Pregnancy.—The following prescription for the treatment of cloasma of pregnancy is quoted by the *Revue de Thérapeutique*:

R.—Zinc oxide	. . .	1 drachm
White precipitate	. .	1½ grains.
Castor oil	. . .	2 drachms.
Essence of rose	. .	10 drops.
Cocoa butter	. . .	2 drachms.—M.

Apply morning and evening.

The Relations between Quinine and Malaria.—The close association of malaria and hæmoglobinuria is undoubted, and in a series of attacks of tertian ague the

earlier ones may be simple, and the later complicated with hæmoglobinuria. To the Italian physicians it is an important question whether the large doses of quinine that they are in the habit of giving do not induce hæmoglobinuria. Tiraboschi discusses the question and describes cases in which hæmoglobinuria began with the administration of 10 grains of quinine three times a day, and others in which the symptom disappeared under the same circumstances. He can find no cases of malarial disease in which quinine alone, without the factor of paroxysmal fever, produced hæmoglobinuria. Consequently he is inclined to attribute little or no influence to the drug in the causation of the symptom. He can trace no clear analogy between any action of quinine and what he considers the two chief sources of hæmoglobinuria, namely syphilis and cold.—*Practitioner*, September, 1890.

Induction of Premature Labor in Contracted Pelvis.—Dr. E. Ahlfeld (*Centralblatt für Gynäkologie*, July 26, 1890) reviews his results of the induction of premature labor in 111 cases of contracted pelvis, and concludes:

1. That the induction of premature labor is a better procedure than Cæsarean section in cases of contracted pelvis, if the conjugate is not less than 7 cm. This is proven by the fact that of the author's 111 cases, only one mother died, and of the 101 children born alive, 61 lived.

2. That Krause's method—the introduction of a flexible bougie—is the best method, and can be performed in a private house as well as in a hospital.

3. The operation should be delayed as long as possible.

4. Under ordinary circumstances induced premature labor should be conducted in the same manner as normal labor.

5. If the life of the mother only is considered the labor should be terminated quickly by rupturing the membranes and evacuating the uterus, but otherwise the membranes should be preserved intact.

Pills for Dysentery.—Boudin, in *L'Union Médical*, September 2, 1890, recommends the following pills for the treatment of dysentery:

R.—Ipecacuanha . . . 5 grains.
Calomel . . . . 1½ "
Extract of opium . . . 1 grain.

To be made into three pills and one given every hour and used either for dysentery or diarrhœa dependent upon exposure to heat.

Ointment for Tinea Tonsurans.—

R.—Caustic potash . . . 30 grains.
Carbolic acid . . . 15 "
Lanolin and cocoa butter each 1½ ounces.
Essence of lavender a sufficient quantity to perfume the mass.

These materials are to be made into an ointment and well applied at night to the affected part, limiting its application to the diseased tissues or a little beyond them. There is generally an improvement after ten days, but in very marked cases relief may not be obtained for as long a period of three months.

Formula for Scrofulosis.—In *L'Union Médical*, August 26, 1890, the following prescription of Guepin for scrofulosis is given:

R.—Iodide of potassium . . 75 grains.
Chloride of ammonium . 30 "
Simple syrup . . . 1½ ounces.
Distilled water . . . 4 "

A teaspoonful of this is to be taken night and morning and may be accompanied by cod-liver oil. The patient, if possible, should stay for as long a time as possible at the seashore.

Syrup for Rheumatism.—The following prescription, recommended by Audhouri, is given for rheumatism:

R.—Iodide of potassium . . 75 grains.
Salicylate of sodium . . 5 drachms.
Syrup of bitter orange peel . 10 ounces.

Of this syrup two to four dessertspoonfuls are to be given each day to an adult for the purpose of relieving the pain and quieting the patient, or if the patient is a child, a coffeespoonful three times a day will generally be sufficient. It is always best to give at the same time that this mixture is administered a small dose of morphine to relieve any pain which may be present.

Treatment of Gonorrhœal Arthritis.—

R.—Camphor . . . . 100 grains.
Extract of opium . . 75 "
Alcohol . . . . 1 drachm.
Extract of belladonna . 75 grains.

This is to be made into a cataplasm and applied over the part from ten to twelve hours, the joint being made immobile by proper dressings.

Insanity and Bright's Disease.—Dr. Alice Bennett has made a thorough study of the relations between Bright's disease and insanity, and in an exhaustive paper read before the Pennsylvania State Medical Society draws the following conclusions:

1. That, contrary to the generally received opinion, affections of the kidney are very common among the insane.

2. That "uræmic poisoning" is one of the most frequent causes of insanity.

3. That while the mental manifestations may be as varied as there are different centres subjected to irritation by these unknown poisons, the most prominent and constant symptom is some form of *mental pain*, which may range from simple depression, through all degrees and varieties of delusions of persecution, self-condemnation and apprehension, with or without hallucinations, up to a condition characterized by a frenzy of fear, with extraordinary motor excitement, and rapid physical prostration—the "grave delirium" or "typho-mania" of some authors.

4. That the motor centres are specially liable to be affected, as evidenced by the restlessness and incessant activity of many cases, less frequently by convulsions and convulsive twitchings; occasionally by choreic movements; occasionally by cataleptoidal states.

Dr. Bennett cites a large number of cases in support of her deductions.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

PHILADELPHIA.

SATURDAY, OCTOBER 4, 1890.

THE TREATMENT OF TUBERCULOSIS OF THE LARYNX.

TUBERCULOUS disease of the larynx is so distressing a complication of a most distressing malady that every observation upon its treatment is deserving of attention. While this condition does occur as a primary localization—a fact long disputed, but finally settled by the studies of J. Solis-Cohen, published in 1881—it is most frequently associated with pulmonary tuberculosis. The special therapeutic problem to be solved, then, is not so much how to bring about the absolute recovery of the patient—for this is bound up with the larger question of the treatment of internal tuberculosis in general, and pulmonary tuberculosis in particular—but how we may bring about healing of the local lesions, or how we may mitigate the sufferings to which those lesions give rise.

It has long been held by competent authorities that in a certain small proportion of cases tuberculous ulceration of the larynx will heal under measures of cleanliness and antisepsis, such as washing with detergent sprays and the insufflation of iodoform—proper attention, of course, being given to general measures of nutrition. Of the truth of this view we can recall a most remarkable instance, that of a patient who came under our observation in 1883, and is still living, apparently well. This man, a commercial traveller, learned how to insufflate iodoform into his own larynx, and for more than a year practised this expedient thrice daily while on his journeys.

It must be admitted, however, that the proportion of such cases is small, and hence, since the discovery of the tubercle bacillus has led to general acquiescence in the theory of the local origin of the morbid processes, renewed efforts have been directed toward discovering feasible methods for radical extirpation of the diseased tissues. Instances from pre-bacillary times were not wanting, in which good results had followed such measures, instituted on the general principles of good surgery. Thus, J. Solis-Cohen, in 1870, excised the epiglottis of a woman with phthisis, on account of limited tuberculous ulceration, and the patient was reported alive and well twelve years later.

The great difficulty in the majority of cases, however, lies in the comparative inaccessibility of the lesions. Tuberculous lymph-glands of the neck, tuberculous joints, and the like, are readily amenable to direct surgical procedures. Manipulations within the larynx are not easy under the most favorable circumstances, and are extremely difficult in the tortured and enfeebled subjects of tuberculous disease. Thyrotomy for better access is not likely to be successful, for the chances are that infection of the wound will prevent healing, and lead to a more rapidly fatal issue. It would be an exceptional, almost unimaginable case, that would justify laryngectomy.

Krause, of Berlin, encouraged by the success of von Mosetig-Moorhof in the use of lactic acid in the treatment of epitheliomata, employed that agent to destroy laryngeal tissues infiltrated with tubercle, and the reports of his good results have encouraged specialists throughout the world to resort to the same procedure.

The larynx being thoroughly cocainized, ulcerated parts are curetted and harshly rubbed with a sponge or cotton wad, saturated with a solution of lactic acid. The strength of the solution varies from 30 to 40 per cent. at first, to from 50 to 80 per cent. finally, according to the severity of the reaction. Chromic acid, the electric cautery, and superficial electrolysis, according to Voltolini's bipolar method, have also been resorted to.

Krause has likewise vigorously applied lactic acid without preliminary curetting, to reduce the infil-

tration of non-ulcerated structures, and he claims excellent results; a claim which has been confirmed by other good observers.

In a communication to the Berlin Congress upon the curability of laryngeal tuberculosis by surgical treatment, Luc (*Archives de Laryngologie*, August, 1890) reviews the various procedures instituted with this object. Many specialists, he says, have not succeeded in obtaining results as brilliant as those reported by Krause, Hering, and others, from curettage and lactic acid, and have, therefore, despairingly fallen back upon purely palliative measures. To illustrate the possibilities of success in radical treatment of accessible lesions, he reports the case of a man, thirty-five years old, affected with tuberculosis of the naso-pharyngeal mucous membrane, in whom Krause's local treatment, combined with superalimentation and other appropriate general measures produced a perfect cure. He also reports a case of limited laryngeal tuberculosis, in which energetic curetting and lactic acid applications had apparently brought about recovery. The patient, however, returned some two months later, after a sojourn in the country, much improved in general health, but with a new local lesion. This latter case, he believes, emphasizes the importance of continuous local treatment; the combination of proper topical applications, with the most approved measures to promote general nutrition, being absolutely necessary in every case.

From a large number of observations the author concludes that the method of Krause is capable of producing good results in well-selected cases; but he deprecates its indiscriminate employment. On account of the pain and distress to which the patient is put, he considers that it is the part of humanity not to resort to this expedient when the condition of the lungs or other organs is such as to render the case absolutely hopeless, or when the laryngeal lesions are so situated that thorough treatment is not possible. On the whole, this is sound advice; though, in certain cases, even with advanced pulmonary lesions, it may be advisable to perform tracheotomy, and then actively curette, and apply lactic acid to the larynx, in the endeavor to avert the difficulty of nutrition, which arises in late stages from the exquisite pain in swallowing, due to the passage of food over ulcerated surfaces. The truth is, that in no disease is more discretion required of the physician in applying general rules to individual cases.

REVIEWS.

Transactions of the American Orthopædic Association. Vol. II. Published by the Association. Philadelphia, 1890.

The development of the various departments of surgery has been so rapid that it is practically impossible for the general practitioner of medicine to follow the advances in the year's work; and although the papers read before the American Orthopædic Association have, in the main, appeared elsewhere, their collection in one volume is most serviceable, since in an hour's reading the subscriber is able to appreciate the best thought and best methods of the most progressive orthopædists.

As would be expected, hip-joint disease is discussed at length, and it is a satisfaction to perceive that the tendency of the present day is not toward conservative treatment.

Dr. W. R. Townsend contributes a paper upon "Acute Arthritis of Infants," tabulating a long series of cases. In the treatment he has nothing new to offer, beyond meeting the well-known indications of suppurative processes.

Dr. DeForest Willard contributes two papers—one upon "Rest and Fixation in Joint Disease," the other upon "The Operative Treatment of Hip Disease." Both of these are characterized by sound common-sense, always noticeable in the writings of this distinguished surgeon.

It is interesting to note that the general drift of all the papers is toward greater attention to what may be called the minor details of treatment; new splints, new applications of old methods are advanced. There is no indication of any radical change of treatment, of any great advance, but in this volume will be found hints and suggestions of the greatest possible value.

Electricity in the Diseases of Women, with Special Reference to the Application of Strong Currents. By G. Betton Massey, M.D. Second Edition, revised and enlarged. Philadelphia and London: F. A. Davis, 1890.

This little volume and the methods which it advocates have been subject to much adverse criticism—criticisms, for the most part, on the part of those ignorant of the principles here set down; but such of his critics as are severe and unjust Dr. Massey can well silence by pointing to the second edition of his work so quickly following the first. Indeed, the popularity of this work is, to a certain extent, a guarantee of its value, or at least an assurance that it is not without value; and of the sincerity of its author none who reads its pages can doubt. The list of cases and of reported cures would be conclusive, were such reports from one man ever conclusive. It will not be until we have the experience of many observers, and of those not primarily in favor of electricity, that a decision as to the true value of this agent as applied to the diseases of women can be reached.

The first few chapters of this work are rightly devoted to a description and explanation of apparatus. Chapter XI. is upon the subject of the electrical treatment of fibroid tumors of the uterus. The author has certainly made out a strong case for his side of the question.

The electrical treatment of uterine hæmorrhage, of subinvolution, of metritis and endometritis, of inflammatory diseases of the uterine appendages, of pelvic pain, of uterine displacements, of extra-uterine pregnancy, and of miscellaneous conditions, are next considered.

It will be a surprise to those opposed to electricity to learn that Dr. Massey has devoted his twentieth chapter to the "Contra-indications and Limitations to the Use of Strong Currents," for according to their statements, it would seem that, in the mind of the electrician, there are neither contra-indications nor limitations. This, however, is unjust and untrue; and, considering the strength of his belief in his methods, Dr. Massey is singularly fair in his conclusions.

SOCIETY PROCEEDINGS.

AMERICAN ORTHOPÆDIC ASSOCIATION.

Fourth Annual Meeting, held at Philadelphia, September 10, 17, and 18, 1890.

(Continued from p. 320)

SECOND DAY—MORNING SESSION.

This day was devoted to the subject of

ROTARY LATERAL CURVATURE OF THE SPINE.

DR. BENJAMIN LEE, of Philadelphia, read a paper on

THE NERVOUS AND MUSCULAR ELEMENTS IN THE CAUSATION OF IDIOPATHIC CURVATURE,

in which he remarked that the maintenance of equilibrium is the first necessity, and that a very small lumbar curve will necessitate a large dorsal compensating curve. It is not strange that the comparatively trifling lumbar curve often goes unnoticed and that the large dorsal curve is the first to attract the attention of the mother or the dressmaker. In fact, in the large majority of cases, the mother does not detect the former even when it has become aggravated, until the surgeon points it out to her. Under ordinary circumstances it is not conceivable that the use of the muscles which move the upper extremity should draw the spine toward the extremity. The extremity must of necessity be drawn toward the spine. We cannot attribute the dorsal curve to direct traction by those muscles, however excessively they may be developed.

DR. CHARLES L. SCUDDER, of Boston, contributed a paper on

THE MUSCULAR ELEMENT IN THE ETIOLOGY OF ROTARY CURVATURE,

which was a preliminary report of an investigation to establish an index of muscular strength in growing girls for each year from the tenth to the nineteenth year of age. The report was based on an examination of the backs of 1041 of the schoolgirls of Boston. The examinations were conducted by means of a chair especially constructed for the purpose, the strength of the back-muscles as a group being measured by a self-registering dynamometer. The results of the investigation show a gradual increase in the strength of the back-muscles of the growing child. The importance of this investigation, as establishing a firm scientific basis for a further study of the muscular element in the etiology, was shown, as well as its bearing upon the treatment, the prognosis, and the recording of lateral curvature cases.

DR. R. W. LOVETT, of Boston, contributed a paper on the

ETIOLOGY OF LATERAL CURVATURE,

and DR. A. B. JUDSON, of New York, one upon the

MECHANISM OF ROTATION IN LATERAL CURVATURE.

Dr. Judson said that rotation is a necessary accompaniment of curvature of the spine in disease and also in health. It may be seen in a thin person when the trunk takes a strong curve to the right or left, and is readily observed in a gymnasium. It is one of the normal functions of the spinal column and adds a sinuous grace to the movements of the trunk. Its cause is found in the fact that when the spine curves laterally, the bodies, forming the anterior part of the vertebral structure, are free to move laterally in the cavities of the chest and abdomen, while the processes forming the posterior part of the column are prevented from the same degree of lateral displacement by being entangled in the parietes, composed of ribs, muscles, and fasciæ.

An important effect of rotation in the deformity produced by lateral curvature is that the curve is greater in the anterior part of the column than in the posterior. A slight curve in the process means a considerable curve in the bodies, and an early diagnosis may be made by looking for rotation rather than for curvature. Rotation may be recognized in a case of incipient lateral curvature by detecting scapular obliquity and a prominence of the transverse processes on the side of the convexity. Its effect on the ribs is to produce an inequality in the diagonal diameters of the chest. In the absence of positive knowledge of the etiology he assumed that lateral curvature is an expression of inability (very likely of nervous origin) on the part of the muscles to hold the spine erect.

He disapproves of the use of braces applied for the forcible arrest or reduction of curvature, as he believes that the mechanical difficulties are too great. A knee can be straightened by applying pressure from before backward in the neighborhood of the joint and counter-pressure from behind forward at points remote from the joint on the long bony levers which compose this joint, but he would not try to straighten by pressure an upright column composed of many short bones thrown into a double or triple curvature with the added complication of rotation at two or three points in opposite directions.

He would advise the patient to avoid fatigue from whatever cause, and to assume for as many hours in the twenty-four as is practicable those attitudes in which there is the nearest approach to symmetry. The patient should sleep supine with lordosis produced by an air pillow. The same position should be assumed a portion of every day. Suspension should also be practised up to, but not beyond, the point of fatigue.

AFTERNOON SESSION.

Papers on the *Treatment of Lateral Curvature* were read by Drs. E. H. Bradford, of Boston, and Henry Ling Taylor, of New York.

THIRD DAY—MORNING SESSION.

DR. JOHN RIDLON, of New York, read a paper entitled

A REPORT OF SIXTY-TWO CASES OF HIP-DISEASE OBSERVED IN THE PRACTICE OF HUGH OWEN THOMAS.

He presented for consideration further facts regarding the use of the Thomas hip-splint. Conclusions could not be drawn from his study of the cases, but he ventured the following suggestions:

Very many of the cases had had the short splint applied before muscular spasm and pain had subsided and before deformity had been reduced, and they had been allowed to walk about without high patten and crutches. Those whose joints had been only partially immobilized, without being protected from the pressure, superincumbent weight, and the concussion of walking, presented a slight degree of adduction, absence of motion, and in a few cases slight flexion, and in one instance in-knee. On the other hand, those cases that had worn a long splint until cured, that remained in the horizontal position till all pain and muscular spasm had subsided and had then used the high patten and crutches, and had had the benefit of intelligent care and nursing, have been cured without flexion or other deformity than a shortening due to actual erosion of bone and arrested growth; a very large proportion have shown motion, and in not a few has there been normal motion.

The average duration of limp before treatment was commenced was, in the 62 cases, a little over ten months. Average duration of treatment was not computed, as only a few cases were cured, and many had been under treatment but a short time. Of the 58 cases that had been under treatment for a longer or shorter time, 24 had shortening, 24 had adduction, 5 had abduction, 3 inward rotation, and 2 had outward rotation. In the cases where abduction coëxisted with the shortening, it was an advantage, as it compensated in a measure for the shortening.

DR. JAMES K. YOUNG, of Philadelphia, followed with a paper on

DISEASES OF THE EYE ASSOCIATED WITH CARIES OF THE SPINE.

He said that the diseases of the eye associated with caries of the spine are, from necessity, of the same pathological nature—strumous or tubercular.

Scrofulosis may be considered the constitutional predisposition to caseation; tuberculosis the same condition infected with bacilli of tuberculosis. Both the lesions of the eye and the caries of the vertebræ yield more readily to constitutional and local treatment combined.

Referring to the relation between scrofula and tubercle, Treves has given the following conclusions;

"1. The manifestations of scrofula are commonly associated with the appearance of tubercle; or, if any fully-formed tubercle be met with, a condition of tissue obtains that is recognized as being preliminary to tubercle. Anatomically, therefore, scrofula may be regarded as a tuberculous or tubercle-forming process.

"2. The form of tubercle met with in scrofulous diseases is usually of an elementary and often of an immature character; whereas in diseases called tuberculous in a strict clinical sense, a more perfect form of tubercle is met with in the form of gray granulation or adult tubercle.

"3. Scrofula, therefore, indicates a milder form or stage of tuberculosis, and the two processes are simply separated from each other by degree."

DR. SAMUEL KETCH, of New York, read a paper on

POSTERIOR RACHITIC CURVATURE OF THE SPINE.

He said that of the deformities of the spine whose underlying cause is found in the condition known as rachitis, those most commonly seen in practice are the lateral and posterior.

The etiology and pathology of posterior rachitic curvature of the spine are essentially those of rickets in general, the deformity being simply one of the local manifestations of a general diathesis. Dr. Ketch believes that the causation is largely mechanical, and furthered by such movements as tend to throw the weight of the body on the weakened vertebræ and their appendages. Rachitis of the vertebræ evinces itself, as does rachitis usually, at a very early period of life, by an irregularity in the process of ossification, by cartilaginous enlargements, and by marked diminution of the harder substances entering into the formation of bone, notably the lime-salts. In consequence of this unstable condition of the rachitic vertebræ we find in the long axis of the spinal column many soft places, in some cases including the upper and lower surfaces of all of the vertebræ, in others localized to a few.

A large number of cases show a limitation of the curve to the dorso-lumbar spine, a favorite position for the occurrence of Pott's disease. In addition to the deformity we may have more or less pain, spinal rigidity, pseudo-paralysis, or any of the distinctive symptoms relating to the area of the disease.

In the treatment of young children from one to two years old, he never advises the use of mechanical supports, the tissues being so unstable that any pressure is apt to be badly tolerated. In such cases the constant recumbent position, with fresh air and sun-baths, together with internal treatment and close attention to the diet, is usually sufficient.

AFTERNOON SESSION.

The following papers were read and discussed:

Relief of Paraplegia, by Dr. A. J. Steele, of St. Louis; Lateral Deviation of the Spinal Column in Pott's Disease, Dr. R. W. Lovett, of Boston; Prognosis of Pressure Paralysis, by Dr. T. Halsted Myers, of New York.

DR. A. B. JUDSON exhibited an apparatus by which it was demonstrated that the strain falling on the tendo-Achillis when a person stands on tiptoe on one foot greatly exceeds the weight of the body. The foot was shown to be a lever, its long arm being the distance from the ankle to the toe, and the short arm extending from the ankle to the heel. In the apparatus shown, the four pounds representing the weight of the body appeared as twelve pounds on the spring-balance which represented the tendo-Achillis. To estimate the tension of the tendon, the weight of the body is to be multiplied by the number of times the distance from the ankle to the heel is exceeded by the distance from the ankle to the toe. If the former is one-third of the latter, in a man weighing two hundred pounds, the tension of the tendo-Achillis is six hundred pounds.

OFFICERS FOR 1891:

President.—Dr. A. B. Judson, of New York.

First Vice-President.—Dr Ap Morgan Vance, Louisville, Ky.

Second Vice-President.—Dr. George W. Ryan, Cincinnati, O.

Secretary.—Dr. John Ridlon, New York.

Place of meeting, Washington, D. C., 1891, in connection with the Congress of American Physicians and Surgeons.

MEDICAL SOCIETY OF VIRGINIA.

Twenty-first Annual Meeting, held at Rockbridge Alum Springs, Virginia, September 2, 3, and 4, 1890.

THE twenty-first annual session of the Medical Society of Virginia convened at Rockbridge Alum Springs, Virginia, Tuesday evening, September 2, 1890, and adjourned Thursday evening, September 4th, to partake of a banquet tendered by the managers of the Springs to the Society and its guests.

The session was called to order by the President, Dr. Oscar Wiley, of Salem, Va. There were also on the stand the Secretary of the Society, Dr. Landon B. Edwards, of Richmond, Va.; the several ex-Presidents of the Society, and the following invited guests: Dr. Landon Carter Gray, of New York City; Drs. Joseph Price and Joseph Hoffman, of Philadelphia; Dr. E. S. Ricketts, of Cincinnati; and Dr. George Herndon, of the U. S. Navy. Among other distinguished visitors at the Springs to whom the same compliment was extended, was General Joseph E. Johnston.

After prayer by the Rev. E. F. Garrison, of Philadelphia, and the cordial address of welcome on the part of the Rockbridge Springs Company, by the resident physician, Dr. J. Edgar Chancellor, of the University of Virginia, DR. JOHN S. APPERSON, of Marion, Va., delivered the

ANNUAL ADDRESS TO THE PUBLIC AND PROFESSION,

in which he dwelt upon the value to the public of regular medical societies.

Following this address, the committee appointed to examine the essays which had been presented for the Hunter McGuire prize of one hundred dollars for the best original essay on the *Diagnosis, Pathology, and Treatment of Chronic Cystitis in the Male*, after having carefully examined each of the seven papers presented, decided that the essay signed "*Causa cessante, cessat effectus*," possessed the greatest merit. On opening the envelope corresponding to this motto, the author was found to be Dr. R. M. Slaughter, of Theological Seminary, Virginia. This essay will soon be published in full in the *Transactions* of the Society, and in the *Virginia Medical Monthly*, and probably in other journals.

Dr. Hunter McGuire, who was present, after awarding the prize by mail (the author not being at the meeting), authorized the announcement that he would award another prize of one hundred dollars at the next annual session of the Society to the practitioner residing in West Virginia, Virginia, or North Carolina presenting the best original essay on some subject that will soon be announced by the Secretary. All essays offered in competition must become the property of the Society, and will be disposed of by it or its Publication Committee.

During the session about one hundred and fifty physicians were in attendance, the total membership being about eight hundred. Nearly fifty new members joined during the meeting. A large number of non-professional men and women were present during the session of the first night, and throughout the several daily meetings Mrs. Mary Young Ridenbaugh, the granddaughter of Dr. Ephraim McDowell, was present as an interested spectator and listener, and received the compliment of being formally introduced to the Society by the President.

SECOND DAY.

At 11 A.M., the President, DR. OSCAR WILEY, delivered his

ANNUAL ADDRESS,

which was retrospective, suggestive, and prospective, as to the profession of Virginia in particular, and was extremely interesting.

THE TREATMENT OF THE SUMMER DIARRHŒAS OF CHILDREN

was the subject selected for a general discussion which occupied several hours. While the discussion was interesting, and some practical points were brought out, nothing was said that indicated a marked advance in our knowledge of the nature and treatment of these diseases.

The appointed leader in the discussion was Dr. C. T. Lewis, of Clifton Forge, Va., who opened the discussion by reading a paper on the subject. Dr. J. N. Upshur, of Richmond, also read a paper.

Extempore remarks were made by Drs. Thomas J. Moore, J. S. Wellford, W. W. Parker, Thomas J. Riddell, and Jacob Michaux, of Richmond; Dr. J. Edgar Chancellor, of the University of Virginia; Dr. T. James Taylor, of Brunswick County; Dr. J. E. Copeland, of Rectortown; Dr. E. T. Brady, of Marion; and Dr. Jacob Simmons, of Obenshain.

During the afternoon the election of officers for the ensuing year took place. The following were elected:

President.—Dr. William W. Parker, of Richmond.

Vice-Presidents.—Drs. J. W. Dillard, of Lynchburg; Jacob Michaux, of Richmond; and H. M. Patterson, of Staunton.

Recording Secretary.—Dr. Landon B. Edwards, of Richmond.

Corresponding Secretary.—Dr. J. F. Winn, of Richmond.

Treasurer.—Dr. Richard T. Styll, of Hollins.

The committees remain about as they were, except that ex-President Hunter McGuire, of Richmond, was made Chairman of the Executive Committee, in place of Dr. Parker, elected President.

Dr. Charles M. Blackford, of Lynchburg, was appointed to deliver the Address to the Public and Profession, in 1891.

Acute Dysentery was selected as the subject for general discussion, which will be opened by Dr. P. B. Green, of Wytheville.

Dr. A. C. Palmer, of Norfolk, was nominated to the Governor of Virginia to fill a vacancy occasioned by

the resignation of a member of the State Medical Examining Board.

On nomination by Dr. Blackford, of Staunton, Lynchburg was chosen as the place for the next annual session; the time of meeting, October, 1891; the day to be fixed by the Executive Committee.

Evening Session.

The evening session was devoted to the section on Ophthalmology, Otology, and Laryngology.

Dr. Robert L. Randolph, of Baltimore, the reporter on the progress of Ophthalmology, spoke of the new treatment of detached retina by injection of tincture of iodine, and of the value of fluoresceïn as an aid in the diagnosis of corneal lesions. He also narrated some experiments of his own and of Kolinski's, with reference to the production of cataract in the lower animals by feeding them on naphthalin.

Dr. William F. Mercer, of Richmond, the reporter on the progress of Otology and Laryngology, spoke of investigations as to the transformation of benign laryngeal growths into malignant growths due to intra-laryngeal operations; the early treatment of naso-pharyngeal and throat affections in young children as a cure or preventive of certain nervous troubles; of nasal intubation as an easy and ready cure of hypertrophy of the soft intranasal tissues and deviations of nasal septa; and of the easy diagnosis of abscess of the antrum by illumination of the maxillary bones by an electric lamp introduced into the mouth. He also spoke of the importance of early recognition and treatment of acute suppurative otitis media following scarlatina.

Dr. Joseph A. White, of Richmond, Va., read an interesting and valuable paper on the

Importance of Nasal Surgery and Nasal Therapeutics in the Treatment of Aural Catarrh.

He also presented a paper by title on the

Relations of Refractive Errors and Muscular Defects in Asthenopia, Ocular Headaches, etc.

Dr. Charles M. Shields, of Richmond, read a paper entitled

When Shall We Operate for Cataract and Strabismus?

He said that a large proportion of cases of cataract in children are zonular, and that an operation is too often postponed until the retina has lost its functional activity. He referred to five cases in his practice, in three of which operation was deferred till the patients were between ten and thirteen years old, but with unsatisfactory results; whereas in two cases—one three years and the other six months old—the results were very satisfactory. As to the age for alternating-strabismus operations, six or seven years is proper; but in the unilateral form of strabismus the earlier the operation the better.

Dr. Alexander Duane, of Norfolk, read a paper on the

Modern Treatment of Strabismus,

contrasting the old methods with the precision of modern operations. Carefully and repeatedly test, he said, the static and dynamic condition of the eyes before operating. In spastic, in periodic accommodative, and in some cases of paralytic squint, treatment of the cause is required; in concomitant and in other cases of paralytic squint an operation is called for. In concomitant strabismus he made a sharp distinction between cases with tendon-tension and those with tendon-relaxation—in the latter advancement, in the former tenotomy being required. He described a remarkable instance of tendon-relaxation in which an apparently divergent squint was immediately benefited by advancement of the external rectus. In paralytic squint he has employed, whenever possible, tenotomy of the antagnostic muscle as recommended by v. Graefe, and, in paralysis of the superior and inferior rectus, advancement of the affected muscle.

Dr. John Herbert Claiborne, Jr., of New York City, forwarded a paper on

Boils in the Ear,

of which the following is a summary: (1) Furunculosis of the external canal is a local disease. (2) The cause is infection by pyogenic microbes. (3) Treatment should consist in local antisepsis, such as applications of solutions of boric and carbolic acids, moist heat, and incisions of the furuncles when they point.

Dr. Laurence Turnbull, of Philadelphia, forwarded a paper entitled

Catarrhal Otitis Media,

in which he condemned most of the so-called hearing-restorers or artificial drums. The only form of artificial covering suited to diseased perforations of the drum-membrane is, he said, delicate gauze or rubber, charged with an antiseptic solution to protect the ear from floating microbes and from temperature-changes. As to the treatment of chronic aural catarrh, in addition to the means mentioned in his book, he suggested, in suitable cases, massage of the ears, valerianate of strychnine, and residence in an elevated region.

Dr. Charles M. Blackford, of Lynchburg, then described a

New Method of Lifting the Epiglottis,

which was devised by Dr. Samuel P. Preston, of Lynchburg. He uses an ordinary silver laryngeal probe, which is bent at a right angle half an inch from the end. Through rings soldered to the shaft the third and fourth fingers of the left hand are passed. Let the bent portion of the probe press down on the glosso-epiglottidean ligaments, so as to tighten them, and this tightening will elevate the epiglottis. The pressure should be gentle.

Dr. Alfred C. Palmer, of Norfolk, described in a short paper a new method of treating deformities of the eyelids, which he termed

Palpo-traction.

He claimed that many distortions of the eyelids might be permanently improved by this conservative plan, but said that it must be applied in infancy when the tissues are pliable and easily moulded by manipulation. He asked obstetricians to pay strict attention to the formation of the lids of newborn infants, and in all forms of entropion, ptosis, and contracted palpebral fissures, to begin at once to shape the lids and retract them to their proper forms and positions.

Third Day.

The Section on Obstetrics and Diseases of Women and Children being called to order, Dr. I. S. Stone, of Lincoln, read a brief paper on the

Diagnosis of Pelvic Disease, and When to Operate.

He said that the profession is united in advising operation for pelvic and abdominal tumors, extra-uterine pregnancy, pyosalpinx, etc., and that electricity in such conditions is hazardous. Salpingitis in country practice is a common result of puerperal diseases, but its symptoms so closely resemble those of pelvic peritonitis and cellulitis as to render the diagnosis impossible. Gonorrhœa is rare in the country, and, therefore, pyosalpinx is not as frequent as in cities. The impossibility of determining the extent of pelvic diseases, and the complications, are the real dangers of operations. He spoke of tubercular salpingitis, and remarked that the cause of each case of pelvic disease should be investigated before deciding to operate. Many cases are aggravated by marriage.
